Thousands of patch reefs, many with coalesced halos, live in the middle of Hawk Channel, mainly off the lower Keys (Figure 4b). No geologic studies have focused on their origin, mid-channel alignment, distribution, and location. Analysis of benthic habitats and bathymetry (Lidz et al., 2006) has resolved their four-part characterization and has revealed a fourth type of coral nucleus new to the Florida record. The patches align along landward edges of two long inner-shelf bedrock troughs within the Hawk Channel depression. The troughs are presumed to consist of grainstone/wackestone, as is found elsewhere in channel bedrock (Shinn et al., 1994).

## Coral spurs and zonations

Holocene corals also formed outer-shelf patch reefs along and parallel to the shelf edge. Though linear, these reefs had seaward spur-and-groove structures in which coral spurs grew perpendicular to incoming waves (Figure 4b; see also Fig. 1 in Chapter Spurs and Grooves). The high-energy shelf-edge setting dictated that the surf-loving branching species *Acropora palmata* would build the spurs. Nearly all margin spurs consist of densely interwoven skeletal *A. palmata* (Shinn, 1963).

**Florida Keys, Figure 3** (a) Cross section of Grecian Rocks shows reef components and uncorrected radiocarbon ages in years before present (year B.P.) of corals recovered in cores. Coral zonation at Grecian Rocks in the 1960s showed five distinct zones. Field observations in 2002 found that most corals including hydrocorals were dead. (b) Cross section of Looe Key Reef (LK) shows that the Holocene reef began accretion on the crest of a Pleistocene topographic high. Note reefs at both sites (a and b) backstepped over carbonate sand. See Figure 2a for locations on reef tract.

**Florida Keys, Figure 5** Cross section of core transect across two rock ridges inshore from U.S. Coast Guard Marker G and southwest of Bahia Honda Key (BH) in the lower Keys (see Figure 2a for locations). Cores were labeled BH because the Bahia Honda Bridge is the only object visible from the outer-shelf core site. Cores show that the ridges are coral reefs, are growing vertically, and are separated by a sediment-filled swale. Note the lack of a Pleistocene trough on landward (NW) side of left coral ridge. Also note the uncorrected radiocarbon ages of recovered corals. The  $37,480 \pm 1,300$   $^{14}\text{C}$  date, obtained on a recrystallized coral, was thought to be much too young due to contamination with younger carbon. Inferred age of bedrock coral sections is between  $\sim 86.2$  and  $77.8$  ka (MIS 5a), which is the age range for the youngest Pleistocene corals on the shelf and for all dated Pleistocene corals in direct contact with Holocene accretions (Toscano, 1996; Multer et al., 2002; Lidz et al., 2003). MIS = Marine Isotope Stage.

Behind the shelf edge, the spur-and-groove system consists of coral zonations (Figure 3a), features that differ from those of the pure *A. palmata* shelf-edge spurs. Zonations result from reef efforts to keep pace with both rising sea level and associated changing wave energy. Deeper water head corals, especially the boulder-coral species *Montastraea annularis*, typically first colonized this type of reef. Their skeletons now form the deepest, most seaward zone (Shinn, 1980). A shallower zone of landward-oriented *A. palmata* followed. Orientation is a response to constant unidirectional high-energy sea swells and waves. Unoriented corals cannot survive in surf because of physical breakage. The third zone is a landward reef flat with unoriented *A. palmata* that grew to spring low tide. The most landward zone is a quiet-water back reef that harbors skeletal colonies of unoriented *A. palmata*, massive species (*Montastraea annularis*, *Diploria strigosa*, and *Colpophyllia natans*), and forests of branching *A. cervicornis*. Though not necessarily of coral zonations, similar classes (fore reef, reef crest, reef flat, back reef) are found at different depths

on most Holocene outer-shelf reefs and are also present in the Holocene record on the largest and most seaward of the lower Keys outlier reefs.

The dominant type (head or branching) and species of coral skeletons in an area are proxies for ambient conditions when the corals were alive. In Florida Keys reefs, massive head corals characterize the Pleistocene, implying quiescent, protected, or deeper water. The promontory landmass was the key (protective) element. *Montastraea annularis* is the dominant species. Branching corals typify the early Holocene, implying active surf. *Acropora palmata* dominated then but is rarely found alive today.

### Key Holocene events and effects

Rising Holocene sea level generated two respective opposing processes (deposition and erosion) of different durations ( $\sim 7$  and  $\sim 4$  ka) at different locations (shelf edge and near shore). Two geomorphic structures unique to the Keys windward-margin record resulted: an

**Florida Keys, Figure 6** (a) Sketch (not to scale) shows interpreted origin of the nearshore rock ledge. (b) Aerial photomosaic (1975) shows the clearly visible ledge (*outlined in short dashes*) that lines the seaward side of all the Florida Keys. Area shown is in the upper Keys (see Figure 2a). A tidal delta at Snake Creek and a muddy bank at Tavernier Key (*long dashes*) cover parts of the ledge. Note the ledge is much wider than the adjacent island, Plantation Key. Plantation Key consists of the emergent Key Largo Limestone coral reef. Total width of ledge and island is consistent with a sloping forereef and a landward reef crest, indicating that the seaward edge of the ledge may represent the seaward extent of the Key Largo Limestone. Bedrock beneath Hawk Channel is grainstone/wackestone (Shinn et al., 1994). Thin sands cover inner part of ledge. Outer part is generally bare rock with scattered patch reefs, especially in lower Keys.

asymmetrically prograded platform and a uniformly eroded nearshore rock ledge.

Seismic profiles show the presence of a discontinuous ~27-m-deep Pleistocene trough behind the discontinuous shelf-edge reef. Where present, the trough along much of the >200-km-long margin has been filled with

landward-transported, storm-derived Holocene sand and reef rubble that, in scattered locations, is topped by skeletal Holocene reefs. Most surface traces of the trough have been obliterated, and infilling has forced progradation of those isolated parts of the shelf surface seaward. Infilling and progradational processes were rapid relative

to geologic time, having taken place only within the most recent ~7-kyr interval of Holocene flooding. Similar progradational evolution is not possible at classic, steeply inclined windward margins. Precipitous (e.g., volcanic) slopes can only aggrade seaward slowly through coral growth.

A nearshore rock ledge ~2.5 km wide cuts into the seaward side of every 125-ka Florida Keys island (Figure 6a and b). Its composition varies depending on northeast (coral) or southwest (oolite) location. Its seaward edge is ~4 m deep. Its landward edge is the shoreline. By definition, an erosional surface cannot be dated. However, correlation of physical ledge characteristics with known post-125-ka Pleistocene sea-level maxima in Florida and a local Holocene sea-level curve provide the only possible explanation as to how and when it formed. The ledge is erosional and formed during the Holocene transgression (Lidz et al., 2006).

### Other aspects

Due to space limitations, other aspects of Florida Keys reefs are not reviewed here. They include coral ecology (Jaap, 1984); effects of sewage-disposal practices (Shinn et al., 1994); diseases (Gladfelter, 1982); biochemical/physical processes, and hydrology/groundwater flow (Porter and Porter, 2002); sediment constituents (Ginsburg, 1956); and reef management (Causey, 2002).

### Summary

The late Quaternary depositional system along the shallow Florida Keys shelf was physically and biologically predisposed to replicate the structures, forms, and processes of antecedent outer-shelf and shelf-edge morphologies. Primary controls were the position of sea-level maxima relative to antecedent topography. Reefs responded to the resultant ambient geomorphic settings in their growth habits, vitality, and distribution. Post-125-ka Pleistocene settings offered accommodation space and protection, and shelf-edge reefs flourished. The Holocene transgression flooded the shelf, ultimately creating conditions that allowed tidal exchange of coastal bay and cold gulf waters with the reefs, causing their decline. The rock record shows that reef growth varied locally through time—in location, dimension, structure, geometry, depth, age distribution, and accretionary direction. Yet the recurring regional theme is the replication of antecedent facies and geomorphic landforms, and thus repetition of stratigraphic shelf-edge asymmetry. Florida Keys reef morphologies are distinctly different from what would be generated at a classic steeply inclined windward margin.

## FORAM INDEX

Pamela Hallock

University of South Florida, St. Petersburg, FL, USA

Benthic representatives of the protistan class Foraminifera have exceptional utility as bioindicators of coastal contamination because they have short life spans and specific niches, and therefore respond quickly to environmental change; they are commonly well preserved in the sedimentary record; they are widely distributed, yet generally regarded as relatively immobile; they are diverse; they are relatively small, abundant, and easily sampled; their collection has minimal impact on environmental resources; and the most stress-tolerant representatives are often among the last eukaryotes to disappear completely from heavily contaminated sites (Yanko et al., 1994; Schafer, 2000). In reef environments, enrichment of nutrients and therefore of organic matter tends to increase abundance and diversity of small, heterotrophic taxa at the expense of the mixotrophic larger foraminifers that host algal endosymbionts. Hallock et al. (2003) developed the Foraminifera in Reef Assessment and Monitoring (FORAM) Index (FI) to provide a simple, non-invasive indicator of whether water quality in the environment is sufficient to support coral-reef growth or recovery. The FI is calculated from foraminiferal-assemblage data from surficial sediments and is based on observations that symbiont-bearing foraminifers and zooxanthellate, reef-building corals require similar high water quality. The FI is somewhat dependent on sediment texture, so sediments dominated by coarse sands or by very fine sands or muds do not provide meaningful data.

The FI enumerates foraminiferal taxa into functional groups, calculated as follows:

$$FI = (10 \times P_s) + (P_o) + (2 \times P_h)$$

where  $P_s = N_s/T$ ,

$$P_o = N_o/T,$$

$$P_h = N_h/T$$

$T$  = total number of specimens counted

$N_s$  = number of specimens of symbiont-bearing taxa

$N_o$  = number of specimens of stress-tolerant taxa and

$N_h$  = number of specimens of other small taxa

The FI was designed as a simple, low-cost, single-metric, preliminary assessment tool to predict if prevailing water quality is sufficient to support coral-reef growth or recovery. The numerical basis for the formula is that an assemblage of 100% other small taxa yields an  $FI = 2$ . Any addition of symbiont-bearing taxa raises the FI, any addition of stress-tolerant taxa lowers the FI from that reference value. An assemblage totally dominated by other smaller foraminifers indicates there is too much food for symbiont-bearing foraminifers to occur in any abundance

(i.e., autotrophic and heterotrophic processes predominate), but not so much (or there is sufficient circulation) that biological oxygen demand in the upper sediments does not become limiting. Where oxygen becomes limiting, stress-tolerant taxa prevail. The more nutrient poor the environment, the more prevalent the mixotrophic taxa become. Calcifying mixotrophs, especially algal symbiont-bearing foraminifers and zooxanthellate corals, also tend to be longer lived and slower growing than their autotrophic and heterotrophic competitors for space, and more sensitive to highly variable oxygen because they have such high respiratory needs at night and produce excess oxygen during the daylight. For  $FI > 4$ , symbiont-bearing taxa must make up at least 25% of the foraminiferal assemblage, providing the basis for the prediction that, if  $FI > 4$ , local water quality should support calcifying mixotrophs.

**Foraminifera, Figure 1** Reticulopodia of *Marginopora* (~1.5 cm in diameter), a reef-dwelling, porcelaneous benthic foraminifer that hosts dinoflagellate endosymbionts similar to those in scleractinian corals.

## Definition and introduction

Members of the Class Foraminifera are among the most abundant and most useful protists in the marine realm. Foraminifers are characterized by a protective shell (commonly called a test), which can be membranous, agglutinated, or calcareous (Sen Gupta, 2002). The shell can be a single chamber or multiple chambers that are interconnected by one or more openings called foramen (plural foramina), from which the class name is taken (<http://www.ucmp.berkeley.edu/people/jlipps/glossary.html>). Foraminifers produce networks of reticulopodia (Figure 1), which are characteristic of the Phylum Granuloreticulosa. The functions of the reticulopodia include motility, attachment, feeding, excretion, and shell construction (<http://www.bowserlab.org/foraminifera/forampage.htm>).

Foraminifers are found in virtually all marine environments. Members of the Order Globigerinida are planktic; all other extant orders are benthic, though some have planktic reproductive stages (Goldstein, 2002). Benthic species live epifaunally, epiphytically, infaunally, or attached to a substrate. A wide range of environmental factors influence where individual species can live and where their shells can accumulate. However, a substantial number of studies have shown that, given suitable physical and chemical parameters, food supply is the primary determinant of population abundances of benthic foraminifers (Loubere and Fariduddin, 2002). Food supply, both quality and quantity, not only provides the energy and raw materials for individual and population growth, but also influences chemical parameters such as dissolved oxygen concentration, pH, alkalinity, and sulfide content at the sediment–water interface and within the sediments (Jorissen, 2002). In settings with excess organic matter (eutrophic environments), respiration reduces oxygen levels so that pore waters become anoxic and sulfidic, limiting habitat depth and foraminiferal abundance in the sediment. In food-limited (oligotrophic) settings, both abundance and depth distributions within sediment are limited by food supply. Intermediate food resources result in expanded gradients in food supply, pH and Eh, supporting more diverse assemblages of epifaunal, shallow-infaunal and deep-infaunal benthic foraminiferal species as compared to either eutrophic or oligotrophic environments.

The shells of individual species and assemblages have exceptional utility as environmental, paleoenvironmental and biostratigraphic indicators in marine environments and sedimentary rocks that originated in marine environments. Features that contribute to that utility include their relatively short life spans and specific niches, and thus relatively rapid responses to environmental change (Hallock

et al., 2003). Foraminiferal shells are commonly well preserved in the sedimentary record; they are diverse, relatively small, abundant and easily sampled, and their collection has minimal impact on environmental resources (Hallock et al., 2003).

While most Foraminifera are microscopic, adults of some taxa can be several centimeters in diameter (Sen Gupta, 2002). Life spans are proportional to size, ranging from days in small taxa to a few years in very large ones. The common life cycle in benthic foraminifera involves alternation of a sexual generation with one or more asexual generations (Goldstein, 2002; <http://www.ucl.ac.uk/GeolSci/micropal/foram.html>). The most common mode of asexual reproduction is multiple fission, which can produce broods of tens to hundreds or even thousands of juveniles, depending upon the volume of the parent cell. Because meiosis can precede asexual reproduction, the broods are not necessarily clones.

As early as the seventeenth century, observers of natural history began noticing the shells and fossils of the Foraminifera (Sen Gupta, 2002). Antoine van Leeuwenhoek and Carl von Linné were among the historic figures who described the complexity of what they assumed were tiny mollusks. In 1835, Dujardin concluded that foraminifera were unicellular. Despite observations of life cycles by Joseph Lister in the late nineteenth century, far fewer scientists have focused on biological studies of foraminifera than on fossil successions, distributions of shells in sediments, and shell geochemistry. Estimates of extant species range from 3,000 to 5,000, and more than 50,000 fossil species have been described (Pawlowski and Holzmann, 2008). Yet life cycles of fewer than 30 species are well documented (Goldstein, 2002). Biological research, including genetic investigations with the potential to revolutionize foraminiferal systematics, is being conducted in only a small number of laboratories worldwide.

Historically, the major groups of foraminifera have been distinguished by wall structure and composition of the shell, including organic-walled and agglutinated forms and those that produce calcareous shells (Sen Gupta, 2002). The calcareous taxa include porcelaneous imperforate and hyaline perforate shells structures, based upon crystalline nature and presence or absence of pores. Loeblich and Tappan (1992) recognized 16 suborders, which Sen Gupta (2002) elevated to orders based on Lee's (1990) elevation of the Order Foraminiferida to Class Foraminifera. Recent phylogenetic work supports assumptions that the porcelaneous taxa are fundamentally different from the hyaline taxa, indicating very early evolutionary divergence of these two lineages (Longet and Pawlowski, 2007).

Organic-walled and agglutinated benthic foraminifera can be found in most marine environments. However, they only dominate in environments where calcareous forms are stressed by reduced saturation of calcium carbonate such as hyposaline (Figure 2), relatively organic-rich, and high-latitude or deep-sea environments (Murray, 2006). Agglutinated taxa that secrete calcite cements are

common in more highly saturated environments, including open shelves and coral reefs.

The most important foraminifera associated with environments of normal or near-normal marine salinities, including coral reefs, are those that produce calcite ( $\text{CaCO}_3$ ) shells (Murray, 2006). Many foraminiferal species use energy to exclude magnesium (Mg) ions during precipitation of calcite, resulting in shells of a few mole% of Mg. However, others, including those of the Order Miliolida that produce porcelaneous shells, precipitate their shells close to equilibrium with seawater, resulting in shells that are as much as 13–15 mole% Mg in shallow tropical waters. Calcite shells containing more than about 8 mole% Mg are relatively soluble when exposed to seawater with reduced carbonate saturation (Morse and Mackenzie, 1990). Thus, the abundance and diversity of Miliolida are good indicators of strong carbonate supersaturation. These forms will likely be among the first to decline as rising atmospheric carbon dioxide concentrations result in progressive ocean acidification (Hallock, 2000).

The other dominant benthic foraminiferal orders that produce calcite shells are the Rotaliida and the Buliminida (Sen Gupta, 2002). However, molecular phylogenetic evidence is emerging that this morphological division will require substantial revision (Longet and Pawlowski, 2007; Schweizer et al., 2008). The Rotaliida include not only some of the most stress-tolerant generalists, but also some of the most highly specialized species found among the Foraminifera (Figure 2). For example, members of the genus *Ammonia* are often the last eukaryotes to disappear from hypoxic or highly polluted habitats (Schafer, 2000). In contrast, Rotaliida that host algal endosymbionts thrive and produce vast volumes of carbonate sediments in extremely nutrient-deficient environments, yet are typically among the first species to decline under anthropogenic pollution (Hallock et al., 2003).

The majority of benthic foraminifera are heterotrophic, feeding on bacteria, algae, detritus, or combinations thereof. Feeding strategies include grazers, detritivores, suspension feeders, herbivores, and carnivores. Some Rotaliida are kleptoplastic grazers, that is, they can utilize the photosynthetic production from chloroplasts that they harvest from algae upon which they feed (Goldstein, 2002).

Several families of Miliolida and Rotaliida have co-evolved with marine algae, diversifying and morphologically specializing to the benefit of their symbiotic relationships (Hallock, 2002; Lee, 2006). The ability of a holobiont (i.e., host with algal symbionts) to both feed and photosynthesize is known as mixotrophic nutrition. This strategy is particularly advantageous in environments where both dissolved nutrients and particulate food are relatively scarce, but energy from sunlight is consistently available, even at quite reduced intensities (Hallock, 2000). Under these conditions, algal symbionts actively photosynthesize, but because they are severely nutrient limited, they excrete most of their photosynthetic products to the host. The host is thereby provided abundant energy

**Foraminifera, Figure 2** Cartoon of some habitats of benthic foraminifera. *Amphistegina* and *Calcarina* are hyaline foraminifera that host diatom endosymbionts; *Peneroplis* is a porcelaneous genus that hosts red algae; *Quinqueloculina* (porcelaneous) and *Rosalina* (hyaline) are small, heterotrophic foraminifera that are abundant in tropical coastal environments with intermediate nutrient input, while *Ammonia* (hyaline) and *Ammobaculites* (agglutinated) are heterotrophic foraminifera that can tolerate strong fluctuations in salinity, oxygen, and other chemical stresses (Drawn by Heidi Souder).

resources for metabolism and carbon-intensive processes such as mucus secretion, shell-matrix production, and lipids needed for reproduction. The few food particles the host can capture can primarily be used for the host's growth and reproduction, with only limited amount of nitrogenous wastes being released to the algal symbionts. Thus, a mixotrophic holobiont has access to literally orders of magnitude more fixed carbon than purely heterotrophic organisms in the same environment (Hallock, 1981).

Thanks to the tremendous energetic advantage of algal symbiosis, lineages of highly specialized foraminifera have evolved in mid to low-latitude reef, shelf, and bank environments several times in geologic history (Beavington-Penney and Racey, 2004). The shells of such foraminifera have been important producers of carbonate

sediments over the past 50 million years, typically associated with coralline red algae, and often with calcareous green algae and scleractinian corals or bryozoans (Pomar and Hallock, 2008). The most famous foraminiferal accumulations are the Eocene Nummulitic Limestones of Egypt, from which the pyramids were built. Similar limestones are present worldwide, where they include major aquifers and hydrocarbon reservoirs.

The algal symbiont-bearing foraminifera are often referred to as larger benthic foraminifera because many species, both extinct and extant, attained exceptionally large adult sizes, in a few cases exceeding 10 cm in maximum diameter (Hallock, 2002). Growth and calcification of substantial-sized shells over periods of months to years can only be sustained by relatively predictable

environments in which adolescent and adult mortality are low and access to sunlight is predictable (Hallock, 1985). However, extreme specialization results in high potential for extinction when environmental conditions change (Hallock, 1987). Larger foraminiferal lineages, like other major calcifying organisms, have diversified and suffered extensive extinctions numerous times in Earth history (Beavington-Penney and Racey, 2004).

A remarkable range of algae have been documented living symbiotically in members of modern families of Miliolida (Lee, 2006). The superfamily Soritacea includes one clade that hosts a rich diversity of dinoflagellate symbionts (Figure 1) similar to zooxanthellae found in reef-building corals (Pochon et al., 2007). A second clade hosts chlorophyte (green algae) endosymbionts, while a third hosts rhodophytes (red algae) (Figure 3). A separate lineage, the fusiform Alveolinidae, host diatom endosymbionts.

Diatoms are the predominant algal symbionts hosted by the Rotaliida families, including Amphisteginidae, Asterigerinidae, Calcarinidae, and Nummulitidae (Lee, 2006). *Asterigerina* are relatively small and morphologically simple, while members of the Nummulitidae have highly specialized internal structures to accommodate not only the symbionts, but also light-gathering and cytoplasmic exchange among chambers and with the environment (Hottinger, 2000, 2006). Individuals of the nummulitid species, *Cyclocypeus carpanteri* (Figure 4) are among the largest foraminifera known, either extant or fossil, with diameters of 6 cm common (Hohenegger et al., 1999).

Foraminifera occur abundantly on coral reefs and associated environments such as reef flats, lagoons, reef slopes, and oceanic banks (Murray, 2006). The Miliolida are particularly diverse, because warm, normal salinity to

slightly hypersaline seawaters are typically highly supersaturated with respect to calcium carbonate, which enhances rates of precipitation of their Mg-calcite, porcelainous shells. Symbiont-bearing Miliolida tend to be most abundant in waters less than 30 m deep (Hohenegger et al., 1999; Hallock, 2002). In the Indo-Pacific, large coin-shaped *Marginopora* (Figure 1) and *Amphisorus*, which harbor zooxanthellae, can be conspicuous in reef flat environments. Western Atlantic and Caribbean reef flats and lagoons are populated by green algae-bearing *Archaias* and *Cyclorbiculina* (Figure 3), which can be extremely abundant on seagrass, macroalgae, and reef rubble.

Rotaliida more often dominate reef assemblages, though species diversity is typically less than for the Miliolida. Smaller heterotrophic taxa, including kleptoplastic species, are common and sometimes abundant. But, relative to foraminifera, modern reef margins and slopes are the domain of the symbiont-bearing Rotaliida. The ubiquitous *Amphistegina lessonii* and *A. lobifera* in the Indo Pacific, and the Atlantic counterpart *A. gibbosa*, often totally dominate foraminiferal assemblages. Where the Calcarinidae (Figure 5) thrive in the Indo-Malay region, they can totally overwhelm even *Amphistegina* (Hohenegger, 2006). In Okinawa, small bottles of beautiful “star sands” are even sold in souvenir shops. Representatives of the Nummulitidae are most common at depths of 30–100 m or more (Hohenegger et al., 1999).

The larger foraminifera in the Indo-Pacific exhibit strong depth zonation (Hohenegger et al., 1999; Renema, 2005), with robust morphologies abundant at less than 10 m depth and increasingly flatter species occurring down to the extreme limits of sufficient light penetration for photosynthesis (Figure 6). Like stony corals, flatter, thinner morphologies are more advantageous as light diminishes with depth.

Biological and ecological studies of foraminifera with algal endosymbionts began in the 1960s, primarily to improve paleoenvironmental interpretations of foraminiferal limestones. As some coral reefs began to exhibit stress and coral cover began to decline in the 1970s and 1980s, abundances of larger foraminifera were observed to trend similarly to coral cover (Cockey et al., 1996). Then, in 1991–1992, *Amphistegina* populations in both the western Atlantic-Caribbean and Indo-Pacific were observed bleaching, providing further evidence that environmental causes of reef decline were also impacting these protists (Hallock, 2000).

Foraminiferal assemblages, especially the abundance and diversity of symbiont-bearing taxa, hold much potential as indicators of water quality decline that can reduce the advantage of mixotrophic nutrition (Hallock et al., 2003). However, the differences in trophic roles of different foraminiferal groups, and the differences in responses to increasing food supply, must be considered when interpreting assemblage data. Researchers often assume that the highest diversities and abundances indicate the most favorable conditions (Murray, 2006). However, in

**Foraminifera, Figure 3** Larger foraminifera from the Florida Keys including *Archaias* (~1 mm in diameter), *Cyclorbiculina* and *Laevipeneroplis* that host green algae as endosymbionts, *Peneroplis* with red algae, and *Heterostegina* with diatom symbionts.

**Foraminifera, Figure 4** A live *Cycloclypeus carpenteri* (~5 cm in diameter), photographed in situ (photo by W. Renema).

**Foraminifera, Figure 5** In situ photograph of live *Baculogypsina* and *Calcarina* (~1–3 mm in diameter) (photo by W. Renema).

warm, shallow, oligotrophic marine environments, where food supply limits abundance and diversity of heterotrophic species (and therefore overall abundance and diversity), dominance by several algal symbiont-bearing species often indicates high water quality. Higher overall foraminiferal diversity and abundance indicates higher nutrient flux, typically from terrestrial sources.

### Conclusions

Reef-dwelling foraminiferal assemblages can be used as indicators of whether water quality supports prolific calcification by symbiont-bearing organisms. However, the total influence of local, regional, and global environmental changes associated with human activities impacts symbiont-bearing taxa somewhat differently than reef-building corals. Thus,

**Foraminifera, Figure 6** Cartoon representation of shape trends with depth in four families of reef-associated larger foraminifera (adapted from Hallock, 2002).

it is important to understand when foraminiferal assemblages respond in parallel with corals and when they do not.

## FOREREEF/REEF FRONT

Guy Cabioch

Institut de Recherche pour le Développement, Bondy,  
CEDEX, France

### Synonyms

Outer reef margin; Outer reef slope; Reef face; Reef slope

### Definition

The forereef is the outside part of a reef seaward of the reef crest (or reef edge) facing open sea.

### Morphology

The forereef is characterized by peculiar morphological features (Guilcher, 1988; Hopley et al., 2007). The most common feature is the inclination of the slope marked by some breaks and sometimes the occurrence of more or less flat terraces or platforms. The forereef is also characterized by the occurrence of spur and groove system in the upper parts, and sometimes by landslides or slipped blocks. Drowned reefs can be unusual morphological features observed in some forereefs. The forereef can be distributed into shallower and deeper zones.

### Factors controlling the morphology

The morphology of the forereef slopes depends on both climatic and tectonic variations and is controlled by several factors including the following (non exhaustive list): (1) the inheritance of morphology (ancient reefs formed during the past sea level variations) (2) the antecedent morphology depending on subaerial exposure and alteration (karstification) during the low stands of sea level; (3) processes of cementation; (4) biological activity taking into account the competition between the various organisms and depending on the degree of water energy and irradiance; (5) collapse and slides resulting from storms, hurricanes, seismic events, or tsunamis; (6) the bioerosion; and (7) the interaction of currents.

### Biozonation

The upper parts of the forereef slope are exposed to the strong wave energy and are characterized by the algal crest in the Indo-Pacific region and by spurs and grooves extending downward. Many boulders and various debris materials can be found. The living corals are generally abundant. In the Caribbean, six types of breaker zones (upper parts of the forereef) were defined depending on the degree of energy of wave exposure (Geister, 1977) displaying some regional variations.

The deeper parts of the forereef slope are generally poorly investigated and consequently little is known from this zone. This area can be marked by steep slope as observed in French Polynesia (Montaggioni et al., 1987) and is characterized by the low degree of water energy and irradiance. Some submersible observations were

performed along the forereef slopes as for example in Jamaica (Land and Moore, 1977) and in Belize (James and Ginsburg, 1979) in the Caribbean, and in Tahiti (Salvat et al., 1985) in the Pacific, where some morphological features were recognized as submerged terraces or series of steps or blocks falling from the above modern coral reefs.

### Biological encrusting zonation

A recent study performed in New Caledonia (Flamand et al., 2008) revealed the occurrence of several biofacies along the forereef comprising mainly bindstones dominated by coralline algal and/or foraminiferal crusts. Based on these observations and taking into account the distribution and abundance of the coralline algae and acervulinid foraminifera depending on the degree of water energy and irradiance, a model of bathymetric range of encrusting organisms was proposed. The coralline algae rich in mastophorids and/or lithophylloids are abundant in the upper parts of the forereef, the coralline algal assemblage rich in melobesoids, *Sporolithon* sp., and *Peyssonnelia* sp. in the deeper parts, and foraminiferal crusts are dominant below 90 m progressively replacing the coralline algal crusts.

### Occurrence of micritic crusts

Laminar micritic crusts were observed in the Red Sea by Brachert and Dullo (1991) on the ledge-rocks from 120 to 200 m. Such crusts were also observed on the forereefs from Belize and Jamaica (James and Ginsburg, 1979; Land and Moore, 1980). In Tahiti, in French Polynesia, relatively thick crusts recovered from 80 to 130 m were interpreted as microbialite crusts (Camoin et al., 2006).

### Summary

The morphology of forereefs mainly reflects the effects of reef growth in interaction with the sea level variations and in combination with the subsidence and uplift movements. Little is known regarding the distribution and the abundance of organisms especially in the deeper parts. Nevertheless, the biological assemblages appear to be distributed characteristically with the water depth depending on the degree of wave energy and irradiance.

## FOSSIL CORALLINE ALGAE

Juan C. Braga  
 Universidad de Granada, Granada, Spain

### Definition

Fossil coralline algae are the remains in the geological record of a group of calcified marine red algae (Corallinales, Rhodophyta), which are common components in coral reef environments and can be significant framework builders.

### Introduction

Coralline algae are the major extant group of calcareous red algae. As a group, they are cosmopolitan and have wide ecological tolerances. They are common on seafloors with low terrigenous supply at depths of up to 100–120 m in all climatic belts. Individual species and genera, however,

have restricted dispersal areas and sensitivity to light conditions, trophic levels, wave energy, salinity, and other ecological factors, all of which limit their geographic and environmental ranges.

The body (thallus) of corallines consists of filaments of cells joined together to form a coherent mass. Most extant coralline algae are pervasively calcified by high magnesian calcite precipitated in the cell walls. In crustose coralline algae (CCA), also known as non-geniculate corallines, all vegetative cells except those at the thallus surface are calcified. Consequently, the entire plant is rigid, with varying degrees of fragility, and a high preservation potential as fossils (Bosence, 1991).

In contrast, in geniculate (articulated) corallines, calcified segments of the thallus are separated by noncalcified joints (genicula). Articulated corallines have bushy thalli formed by branches for which the joints offer flexibility. After death, articulated corallines disintegrate and calcified segments are shed as sand and gravel particles.

CCA are common components in coral reef environments and can be major framework builders in algal ridges (Adey, 1986). Accordingly, CCA are significant components in fossil coral reefs (Figure 1). Like their living counterparts, fossil CCA can occur attached to hard substrates, typically coral skeletons, cemented reef rock, shells, and other calcified algae. CCA can also be unattached, occurring as nodules generally termed rhodoliths or as loose branching growths within gravel or sand deposits. Fragments of CCA and calcified segments of geniculate corallines are abundant in reef debris and carbonate packstones and grainstones associated with fossil reefs.

Diagnostic features for delimiting families and subfamilies and many diagnostic characters used to separate genera and species can be recognized in fossil plants in ultrathin sections (less than 20 microns) with an optical microscope (Figure 2) and scanning electron microscope (SEM) after light etching (Braga et al., 1993). In some cases, however, the diagnostic characters to distinguish genera and species in living corallines correspond to uncalcified reproductive structures that are not preserved or are difficult to discern in fossil corallines. Fossil plants of the majority of the main CCA species of modern reefs usually preserve characters that permit their identification. In a few cases, the preserved anatomic features only warrant the identification of a species group within a genus. A species group is a set of species that share a series of characters separating them from other species of the genus. Plants with very thin laminar thalli (less than 0.02 mm in thickness) are commonly micronized and usually cannot be identified. Therefore, they are not taken into account in palaeoenvironmental interpretations based on fossil CCA.

### Applications of fossil CCA

The habitat preferences of different genera and species, the variations in morphology according to turbulence

**Fossil Coralline Algae, Figure 1** Last deglacial reef framework in Tahiti. Coralline algae (white) encrusting branching corals (beige) and overgrown by a laminar coral (beige, top right). Crustose coralline algae (CCA) are intensely bored by sponges.

levels, and their high preservation potential make fossil CCA very useful palaeoenvironmental indicators (Adey, 1986). Light is the primary factor controlling the distribution of CCA species and, as light intensity and wavelength reaching the seafloor strongly depends on depth, CCA species have limited depth ranges. The ranges of CCA genera are less defined, but some genera show distinctive depth zonation. CCA genera and several of their species living in coral reefs have a pantropical distribution. Other species are held to be “paired,” occurring as vicariant species, playing similar ecological roles, in the Caribbean and in the Indo-Pacific. In cases where taxonomic revisions have been undertaken, they have shown that species pairs are actually heterotypic synonyms.

CCA taxa have a slow rate of morphological evolution and high longevity (Bosence, 1991). As result of this trait, the immense majority of coralline taxa identified in Quaternary reefs are living today and their present-day environmental distribution can be used to interpret the palaeoenvironments in which they lived. In particular, depth ranges of living CCA can be applied to discern the palaeobathymetry of the deposits in which fossil CCA occur.

Assuming that CCA species, species groups, or genera are correctly identified, certain other aspects might limit the validity of this “transferred ecology” approach. First, any postmortem displacement of fossil plants from their original habitat has to be discarded. CCA encrusting corals in reef frameworks offer the most positive proof of in situ preservation. In contrast, taphonomic and sedimentological observations are needed to convincingly assume the absence of transport of rhodoliths or algal fragments occurring in gravels and sands. Second, the understanding of the ecology of present-day corallines is uneven and limited for many areas. The depth distribution of CCA is relatively well known only from a certain number of regions through field guides and monographic papers. The reported depth ranges are patently affected by sampling depth and probably by the area surveyed, and therefore the data for a single taxon from different regions are not always coincident. In addition to biases introduced by surveying procedures, factors influencing light penetration (such as turbidity) can also affect the depth distribution of CCA species. Even though the majority of genera and many species in living reefs probably have broadly similar ecological requirements across the oceans, their depth ranges may vary between areas. Ideally, the palaeoenvironmental interpretation of fossil corallines in a Quaternary reef should be based on the ecological distribution demonstrated by the species living in the same area. Third, some taxa may change their environmental requirements over time, although this factor is probably negligible for late Quaternary reefs.

Summarizing available data on the environmental distribution of modern CCA from the last few decades (Adey et al., 1982; Adey, 1986; Verheij and Erftemeijer, 1993; Iryu et al., 1995; Cabioch et al., 1999; Littler and Littler, 2000, 2003), three distinct zones can be defined by

**Fossil Coralline Algae, Figure 2** Microphotograph of Pleistocene *Hydrolithon onkodes* in thin section.

the depth ranges of genera and species (Figure 3). This zonation follows the one proposed by Webster et al. (2009) for reef facies in Quaternary Pacific reefs. The main components of these zones and their characteristic growth forms, together with the resulting carbonate facies, are summarized below.

**Zone 1.** Shallow coral reef (0 m to 15–20 m). This zone is dominated by coralline frameworks in which CCA encrust massive and branching corals and intergrow with encrusting corals and other sessile organisms. In the Indo-Pacific, centimeter-thick plants of *Hydrolithon onkodes* dominate the algal assemblages at less than 10 m (Figures 1 and 2). Thin crusts of *H. onkodes* and several species belonging to the subfamily Mastophoroideae, such as *Hydrolithon gardineri*, *Hydrolithon munitum*, *Hydrolithon reinboldii*, *Neogoniolithon fosliei*, *Neogoniolithon frutescens*, *Pneophyllum conicum*, and *Spongites yendoi* are also common throughout this shallow-water zone. Large rhodoliths formed by plants of these species occur in back-reef areas and lagoons. Branching plants of the *Lithophyllum kotschyannum* species group occur attached to the reef framework or forming rhodoliths in the lagoon gravels and sands. In the Caribbean, *Hydrolithon pachydermum* plays the role of *H. onkodes* in the Indo-Pacific. *Lithophyllum congestum* occurs in reef crests and other *Lithophyllum* species extend to deeper settings. Branching growths of *Neogoniolithon strictum* form open frameworks and rhodoliths in back-reef areas and lagoons. CCA that are typical of deeper zones (such as *Lithothamnion*, *Mesophyllum*, *Lithoporella*, and *Sporolithon* species) can overgrow

the shallower-water species mentioned in the paragraph above or encrust the same coral colony on a different side. This occurs since light controls coralline distribution, and therefore shade habitats in the framework, such as crevices, caves, and cavities, are dominated by the same CCA as those living in open deep environments. Similarly, shallow-water species can be overgrown by shade species when the framework substrate in which they grew becomes overshadowed by new coral growth. In fossil reefs, this zone is represented by in situ coralline frameworks (framestones, bindstones, and bafflestones) or CCA crusts on large coral fragments.

**Zone 2.** Intermediate fore-reef slope (15–20 m to 50–60 m). CCA occur as rhodoliths in gravels and sands in the reef slope or as crusts on hard substrates (minor corals, lithified reef deposits). Rhodoliths are typically formed by thick fruticose and warty layers of CCA. In the Indo-Pacific, *Mesophyllum erubescens* and *Lithophyllum prototypum* (also reported as *Titanoderma tessellatum*) are typical of the shallower part of this zone. *Hydrolithon reinboldii*, *Lithothamnion prolifer*, and *Lithophyllum acrocamptum* are common down to 40–50 m. *Mesophyllum erubescens* and *Lithophyllum prototypum* also occur in this zone in the Caribbean, together with *Hydrolithon boergesenii*, *Neogoniolithon* species, and *Lithothamnion ruptile*. In fossil reefs, this zone is characterized by rhodolith floatstones and rudstones and CCA bindstones with encrusting foraminifers and with minor corals.

**Zone 3.** Deep fore-reef slope (50–60 m to 120 m). The lower limit of CCA distribution is usually around 120 m, but thin plants can grow on much deeper settings

**Fossil Coralline Algae, Figure 3** Depth ranges of common CCA in the Indo-Pacific reefs. Depth zonation of an idealized back reef/reef slope transect, which can be applied to interpret palaeodepth in fossil reefs.

(down to 270 m, Littler et al., 1985). CCA occur as nodules in carbonate sands or as thin crusts on hard substrates frequently intergrown with encrusting foraminifers, forming complex, multigenerational open frameworks. The genera *Lithothamnion* and *Mesophyllum*, belonging to the subfamily Melobesioideae, dominate the algal assemblages together with *Sporolithon* and the red alga *Peyssonnelia* both in the Indo-Pacific and the western Atlantic. *Lithoporella* is also common in this zone in the Indian and Pacific oceans. In fossil reefs, this zone is represented by rhodolith floatstones and rudstones, and coralline algal and foraminiferal crust-dominated bindstones, with the above-mentioned algae.

This zonation model can be applied to interpret the palaeobathymetry of fossil CCA and the reef deposits in which they are found. Since deeper-assemblage species may occur with those characteristic of shallower depths, the zone is identified by the maximum depth range of the shallowest CCA present.

The relative abundance of CCA is indicative of water turbidity as the CCA cover in modern reefs is higher in clear waters with no terrigenous influx (Fabricius and De'ath, 2001). Species richness is probably correlated to water clarity as well.

## Summary

Coralline algae, particularly the crustose species (CCA) are common components in fossil coral reefs. CCA

possess a calcitic skeleton with a high fossilization potential.

Fossil CCA occur attached to hard substrates or unattached, as nodules or as loose branching growths and fragments within gravel or sand deposits. The majority of CCA species identified in Quaternary reefs all over the world are living today and their present-day habitat preferences can be used to interpret the palaeoenvironments in which they lived, especially palaeodepth. Three depth zones can be distinguished according to available data on the depth ranges of modern CCA. These zones can be applied to infer palaeobathymetry in Pleistocene and possibly older reefs. Zone 1, in the shallow coral reef (0 m to 15–20 m) is characterized by thick CCA crusts on corals. Thick plants of *Hydrolithon* and other species of the subfamily Mastophoroideae and branching plants of *Lithophyllum* are common throughout this shallow-water zone. Large rhodoliths formed by these species occur in back-reef areas and lagoons. In Zone 2, in the intermediate fore-reef slope (15–20 m to 50–60 m), CCA occur as nodules in gravels and sands in the reef slope or as crusts on hard substrates. Several species of *Mesophyllum*, *Lithothamnion*, *Lithophyllum*, and *Hydrolithon* appear in this zone. The melobesioids *Lithothamnion* and *Mesophyllum*, together with *Sporolithon* and the red alga *Peyssonnelia* are typical of Zone 3 (50–60 m to 120 m or more). In this deeper fore-reef slope, CCA occur as nodules in fine reef debris or as thin crusts, commonly intergrown with encrusting foraminifers on hard substrates.

## FRINGING REEF CIRCULATION

Kevin E. Parnell  
 James Cook University, Townsville, QLD, Australia

## Synonyms

Fringing reef hydrodynamics

## Definition

Fringing reef circulation is the flow of water generated by wave, tide, and wind generated currents, over and adjacent to fringing reefs and in their associated lagoons, including flow patterns resulting from water movements interacting with elements of the reef morphology.

## Introduction

Fringing reefs have been described as being morphologically simple (Kennedy and Woodroffe, 2002), but variation in important parameters such as the reef morphology, tidal range, and wave energy means that a widely applicable model of fringing reef water circulation does not exist. Fundamental distinctions can be made between fringing reefs with or without an enclosed lagoon, those on the windward shores (with circulation normally driven by waves) or leeward shores (with tidal and other currents dominating), and those enclosed by headlands (where topographically controlled circulation is important) or those that extend along a more or less straight shoreline. Other reef types that could be described as fringing are variously described as either fringing or barrier (e.g., Ningaloo Reef, Australia; Hearn, 1999), bank-fringing (e.g., Great Pond Bay, St Croix, U.S. Virgin Islands; Lugo-Fernandez et al., 1998b), bank-barrier (e.g., Tague Reef, St Croix; Lugo-Fernandez et al., 2004), or coral lagoons (e.g., Kaneohe Bay, Oahu, Hawaii; Hearn, 1999). Other authors have described reefs adjacent to coral cays as fringing (Daly and Brander, 2006).

## Waves and wave generated circulation

Wave driven circulation on coral reefs has received considerable attention, with many processes on both fringing and non-fringing reefs being generally similar. When waves reach a reef, shoaling is rapid and the surf zone is narrow, with most energy expended over a short distance at the reef edge or at the reef crest. Most energy (60–97%) is lost during the wave shoaling, breaking, and reforming processes (Gourlay, 1994; Lugo-Fernandez

et al., 1994; Daly and Brander, 2006), with energy dissipation due to bottom friction contributing significantly to, and perhaps dominating, the overall energy reduction (Lugo-Fernandez et al., 1998a; Lowe et al., 2005). A relatively small proportion of the wave energy reaches the back reef or lagoon. Tidal range is an important controlling factor (Hardy et al., 1991a, b) because of its influence on the water depth over the reef crest. At low tide, little or no wave energy crosses the reef flat. At mid tide, most waves break, energy is dissipated, and some waves re-form as bores, passing over the reef flat as solitary waves and reforming (if a lagoon is present). At high tide, waves may break and reform, or under low energy conditions or in situations with a high tidal range, waves may pass over the reef crest onto the reef flat or into the lagoon, and travel to the beach with little loss of energy. Lugo-Fernandez et al. (1998b) reported an average 62% wave attenuation between the fore-reef and the reef crest and 90% attenuation between the fore-reef and the back-reef lagoon, in the low tidal range environment of St Croix., with wave attenuation being significantly higher at low tide. Following breaking, a broadening of the wave spectrum occurs (Young, 1989; Hardy and Young, 1991). A maximum for the wave limiting parameter (wave height/mean water depth) of about 0.55 as reported by Gourlay (1994), Nelson (1994), and Kench and Brander (2006) is applicable to fringing reefs.

Some studies have demonstrated that infragravity waves, perhaps generated by shelf resonance, can be significant (Roberts and Suhayda, 1983), although their overall importance remains unclear (Lugo-Fernandez et al., 1998c). Low frequency resonance is also described by Peguignet et al. (2009), who hypothesize that during high energy events, resonance leads to a significant increase in wave energy reaching the shoreline.

Wave setup is of prime importance in driving water across the reef crest into the lagoon or onto the reef flat on fringing reefs. Lowe et al. (2009) found wave setup to be roughly proportional to offshore wave energy flux, above a lower threshold where setup was minimal. Jago et al. (2007), in a study on the (non-fringing) Lady Elliot Island (Great Barrier Reef) reef, demonstrated secondary wave setup on the beach, a factor not incorporated into previous models. The effects of setup on reef water circulation is described by Gourlay (1996a, b) and Gourlay and Colleter (2005). Symonds et al. (1995) showed reef and lagoonal currents were proportional to off-reef wave height after tidal effects had been removed. Hearn (1999) introduced the concept of current depth coefficients on the basis of studies in Kaneohe Bay and on Ningaloo Reef, predicting a linear relationship between the height of incoming waves and the speed of the current across the reef and through the lagoon. However, although modeling studies of wave setup on reefs now abound, field verification remains limited, and important assumptions have not been tested. Importantly, Hearn (1999) points out that variable wave friction which is dependent on depth means that the hydrodynamics of fringing reef

systems is highly non-linear, and this is a severe restriction for laboratory or modeling studies.

Many studies emphasize the importance of channels for water returning to the open sea (e.g., Roberts et al., 1975; Roberts, 1981; Marsh et al., 1981; Yamano et al., 1998; Lugo-Fernandez et al., 2004). Setup generated flow drives water into the lagoon (where one exists), and balance is maintained by preferential return flow through channels (Lowe et al., 2009), a process analogous to rip formation on beaches (Roberts, 1981). Longshore currents develop to carry water to the channels. Velocities in channels up to  $1.5 \text{ ms}^{-1}$  are reported by Coronado et al. (2007), with maximum currents within the lagoon being  $0.6 \text{ ms}^{-1}$ , which is in the same order as reported by other studies (e.g., Marsh et al., 1981). Tamura et al. (2007) show that although flows towards channels are expected to dominate when wave-generated flow into the lagoon is significant, the same circulation pattern exists even when wave energy is small, despite the presence of tidal currents. Jago et al. (2007) note that it is generally assumed that a return to the mean water level landward of the reef to the open ocean water level takes place by flows through a lagoon. In cases where a lagoon does not exist, as is the case on many fringing reefs, it is suggested that alongshore variation in wave setup drives along reef flows which have the same function as cross-reef directed flows through lagoon openings.

### Wind-generated circulation

When wave energy is low, circulation can be dominated by flows generated by trade-winds. Roberts (1981) reports that currents of  $0.5\text{--}0.8 \text{ ms}^{-1}$  for durations of 2–6 s are common under such conditions, although typical wind generated flows are in the range of  $0.10\text{--}0.25 \text{ ms}^{-1}$ . Presto et al. (2006), in a study on Molokai, Hawaii, showed that trade-wind generated flows dominated circulation and sediment flux. In a study on the Puerto Morelas fringing reef system, Mexico, Coronado et al. (2007) found trade wind generated flows were small, and concluded that wind influence through wind-wave generation was the most effective wind influence. Trade-wind generated waves were also reported to increase sediment suspension by Storlazzi et al. (2004).

More generally, on wide reef flats or in wide lagoons, high-frequency wind waves can be generated, the frequency and direction of which can be quite different from those of waves that have traveled from the reef edge (Kench and Brander, 2006).

### Topographically controlled circulation

At a regional scale, circulation on fringing reef shores is dominated by larger scale circulation related to features such as shelf waves and tides, modified locally by the influence of waves (Monismith, 2007). In these cases, where fringing reefs interact with regional circulation, reefs will generate large scale three dimensional eddies, similar to those shed by any topographic feature in moving

**Fringing Reef Circulation, Figure 1** Fringing reef eddy circulation in the lee of a headland (a) plan view (b) side view (Hopley et al., 2007).

water (Wolanski, 1986). At smaller scales, wave-driven circulation might be expected to dominate on windward coasts, whereas on leeward shores, the interaction of tide-generated or wind-generated currents with the local topography will set up topographically controlled circulation patterns, with eddy circulation dominating.

Eddies were found to dominate circulation on embayed fringing reefs in the Great Barrier Reef region (Figure 1) (Parnell, 1988a, b). The radius of the eddy was dependent on the incident angle between the headland shedding the eddy and the current, the degree of indentation of the bay, and the morphology of the reef front (Hopley et al., 2007). The radius of the eddy was greatest where the incident angle was highest and the eddy was strongest where the bay was enclosed by headlands at each end, with water being deflected against the opposing shore. Eddy circulation was established quickly following the establishment of a tidal stream. Velocities within the eddy (over the reef flats) were found to be independent of tidal stream velocities and generally less than  $0.2 \text{ ms}^{-1}$ . Wolanski (1993) identified the presence of a narrow free shear layer (an area inhibiting water circulation across it) extending to the seabed and comprising numerous small eddies, in such situations. Lines indicating the shear can often be seen extending a considerable distance downstream of headlands. Eddy circulation was accompanied by upwelling of water at the reef front.

## Flushing

Water circulation is the most important driver of flushing (alternatively called turnover or residence). The parameters used to measure flushing vary widely between studies and direct comparisons are normally impossible. Flushing is strongly influenced by the presence (or absence), nature, and size of a lagoon. Residence times can vary significantly by an order of magnitude for different parts of a system, such as in Kaneohe Bay, where areas with physical separation from the ocean can have residence times of 1–2 months (Lowe et al., 2009). Some studies, for example Kraines et al. (1998), report very short (<5 h) residence times in a shallow lagoon system using calculations based on the flow field. Headland enclosed fringing reefs

with no lagoons and with well developed eddy circulation are typically very well flushed (Parnell, 1988a), with residence times of close to one tidal cycle on spring tides.

## Summary

Fringing reef circulation varies depending on a range of factors, the most significant being wave energy, the presence or absence of a lagoon, the presence of channels through the reef front, and the nature of topographically controlled circulation. Wave setup driven flow is the most important driver in windward locations, with trade-wind generated flows or tidal flows interacting with local topography being most important in leeward locations.

## FRINGING REEFS

Scott Smithers  
 James Cook University, Townsville, Australia

## Definition

“Fringing reefs” are reefs that grow very close to the shore on mainland or high island (continental shelf or volcanic mid-ocean island) coasts. They are generally shore-attached, although back-reef areas can be shallowly submerged. Most fringing reefs are simple structures geomorphologically which can be divided into three main zones: forereef, reef crest, and backreef. They tend to be relatively narrow reefs where the submarine slope is steep and broader where it is gentle, and they usually consist of a thin but seaward thickening veneer of reefal carbonate deposited over a rocky substrate. Fringing reefs are the first in the subsidence-driven Darwinian reef sequence (fringing reef – barrier reef – atoll; Darwin, 1842). They are often relatively young reefs and tend to be best developed on stable or rising coasts.

## Introduction

In the 30 plus years since Steers and Stoddart (1977) suggested that

*Of the three main types, fringing reefs are the simplest, apparently the least in need of complex explanations, and also the least studied.*

There have been numerous geomorphological studies of fringing reefs, including morphostratigraphic and geochronological investigations. These studies show that although many fringing reefs are relatively thin structures of recent age, their growth and development is usually more complex than formerly recognized. Kennedy and Woodroffe (2002) provide an excellent review of geomorphological research on fringing reefs that summarizes this complexity. The proliferation of fringing reef research since the late 1970s occurred partly because they are the most common type of reef (more than 50% of the total reef area globally – Hopley, 2004), and they are relatively easy reefs to access compared to those offshore, but another significant motivation has been their perceived vulnerability to threats associated with land-based human activities (see *Nutrient Pollution/Eutrophication*). In recent years, this interest has intensified as many fringing reefs are reportedly in decline, even on the Great Barrier Reef (GBR) – the world’s best protected reef ecosystem (e.g., McCulloch et al., 2003; Fabricius, 2005; Wilkinson, 2008) (see *Great Barrier Reef: Origin, Evolution, and Modern Development*).

Following Darwin’s classification (1842) (see Darwin, Charles (1809–1882)), fringing reefs are interpreted as the first stage in a long-term evolutionary sequence, in which reef growth is initiated over a substrate on the shoreline where it simply grows upward and outward (Figure 1a), but later becomes separated from the shore as the underlying substrate gradually subsides and a leeward lagoon develops (see *Subsidence Hypothesis of Reef Development*). Fringing reefs are thus widely associated with stable or uplifting coasts, where the lack of subsidence impedes the transition from fringing to barrier reef. However, as

discussed later in this entry, slow geological subsidence has generally had little influence on modern fringing reef growth compared to more rapid changes in relative sea level throughout the Holocene (see *Postglacial Transgression: Sea-Level Change and Its Effects on Reef Growth*).

A water depth over the backreef of less than 10 m is usually the principal criterion used to define a reef as a fringing reef (Milliman, 1974). A narrow back-reef lagoon width has also been suggested as a trait that differentiates fringing from barrier reefs (e.g., Purdy and Winterer, 2006), but as no quantitative standards are provided, this subjective diagnostic criterion is of little value. The distinction between fringing reefs and barrier reefs can be ambiguous, with Tayama (1952) proposing a transitional class termed “almost-barrier” reefs based on his observations through Micronesia. Intermediate forms have been described at sections of the Huon Peninsula, Papua New Guinea, where the reef crest is separated from the shoreline by a depression deeper than is usual for a fringing reef (Chappell, 1974), and laterally reefs may vary from fringing to barrier in character, as is the case along the Kenyan coast (Bird and Guilcher, 1982).

Most attempts to understand fringing reef development focus on the influence of two primary controls:

1. The adjacent landmass, specifically its lithology and topography, and the delivery of freshwater runoff, nutrients, and sediments to inshore waters (Guilcher, 1988)
2. The pattern of relative sea-level change (the combined influence of sea-level change and tectonic stability) during the postglacial transgression (see *Postglacial Transgression*) (Adey, 1978), which together with the topography of the substrate provides the accommodation space (see *Accommodation Space*) in which a fringing reef may grow (e.g., Tudhope and Scoffin, 1994; Smithers et al., 2006)

The rate and mode of accretion at some fringing reefs has also been significantly affected by the regional storm

**Fringing Reefs, Figure 1** (a) Classic fringing reef growth *sensu* Darwin; (b) incipient fringing reef growth and development (After Chappell et al., 1983).

climate (e.g., Blanchon et al., 1997; Braithwaite et al., 2000) (see *Tropical Cyclone/Hurricane*). These factors combine to produce fringing reefs that may on the surface appear simple (as described by Stoddart and Steers, 1977), but which morphostratigraphic and geochronological investigations of a broad sample of fringing reefs from around the world show may be produced by a variety of different growth models. The aims of this short review are to examine the main factors that control fringing reef development in its various modes and to describe the main features common to most fringing reefs.

### Fringing reefs and terrestrial influence

By definition fringing reefs are closely associated with adjacent landmasses. These landmasses fundamentally influence fringing reef development by providing the substrate on which most develop. Another consequence of this relationship is, however, that fringing reefs are more directly exposed to freshwater, nutrients, and sediments – natural and anthropogenic – shed from coastal catchments, which may inhibit coral growth (e.g., Cortes et al., 1994; Furnas, 2003; McCulloch et al., 2003; Fabricius, 2005) and influence reef development (e.g., Bellwood et al., 2004). The nature of these interactions is outlined below.

### Fringing reef substrates

Many fringing reefs do grow over rocky substrates as suggested in classic models of fringing reef development. In mid-ocean settings, drilling (see *Drilling*) through the entire reef sequence has, for example, established volcanic foundations for the fringing reef at Hanauma Bay, Oahu, Hawaii (Easton and Olson, 1976) and at Pointe-au-Sable Reef, Mauritius (Montaggioni and Faure, 1997). On high islands and mainland coasts bedrock foundations for fringing reefs have similarly been established (e.g., at the north and northeastern end of Grand Terre, New Caledonia [Cabioch et al., 1999], at Phuket [Scoffin and Le Tissier, 1998], and at Punta Islotes, Costa Rica [Cortes et al., 1994]). The suitability of these stable substrates for coral colonization and reef growth is demonstrated by the rapidity with which reefs form on recent volcanic islands; Umbgrove (1930) described incipient fringing reef growth at Krakatoa less than 50 years after its catastrophic eruption (see *Volcanic Disturbances and Coral Reefs*). Although rock substrates are widely perceived as optimal for reef initiation and growth due to their stability and elevation above the sea floor (Veron, 1995), on the GBR where more than 25 fringing reefs have been cored – only at Scawfell Island on the southern GBR is the possibility of a bedrock foundation suggested, despite the widespread availability of headlands (Kleypas, 1991).

As additional coring data from fringing reefs have become available it is evermore apparent that fringing reefs can rise from a variety of foundations. Although fringing reefs less commonly develop over Last Interglacial (LIG) or older reefs (see *Last Interglacial and Reef Development*) than barrier reefs or atolls, drilling

has confirmed a pre-Holocene reefal basement for many fringing reefs including Australia's largest fringing reef – Ningaloo Reef, Western Australia (Collins et al., 2004), fringing reefs in the Ryukyu Islands of Japan (Kan et al., 1995; Webster et al., 1998), those on the south and southwestern shores of Grande Terre, New Caledonia (Cabioch et al., 1999), and for many fringing reefs throughout the Caribbean (e.g., Milliman, 1973; Hubbard et al., 2005). Different carbonate deposits of varying age underlie other fringing reefs, including Miocene calcareous siltstones at Galeta Point, Panama (Macintyre and Glynn, 1976), and eolianites at Lord Howe Island (Woodroffe et al., 2005) (see *Eolianite*).

The occurrence of unconsolidated sediments, often very fine, on the seafloor in nearshore environments is not unexpected given the proximity to fluvial and other sources. However, the frequency with which fringing reefs have grown over these foundations is more surprising given the difficulties that such substrates present for coral settlement and growth (see *Corals: Environmental Controls on Growth*). Nonetheless cores through many Holocene fringing reef sequences terminate in either Holocene siliciclastic deposits, sometimes mixed with reefal carbonates (Perry, 2003; Perry and Smithers, 2006), or in Pleistocene clays (Hopley et al., 1983; Perry and Smithers, 2010). In several instances fringing reefs have established on deltaic deposits of alluvial cobbles (Partain and Hopley, 1989) where fluvial discharge of water and sediments have clearly in the past been significant (see *Turbid Zone and Terrigenous Sediment-Influenced Reefs*), and at others Pleistocene boulder beaches appear to have been colonized by reefs in the Holocene (Hopley and Barnes, 1985; Perry and Smithers, 2009) (see *Boulder Beaches*).

The topography and spatial extent of the substrate can exert considerable influence on fringing reef morphology and geometry (Davies and Marshall, 1979), although the effects of both usually diminish with time (Macintyre and Glynn, 1976). At the most basic, on steep shorelines the extent to which the fringing reef may prograde seaward is limited by the depth of the foundations so that typically narrow reefs develop – vigorous reef growth is restricted to within 50 m or so of the surface (see *Corals: Environmental Controls on Growth*). In contrast, where the substrate is more gently sloping, the reef may construct a broad reef flat extending hundreds of meters offshore. As discussed in section “Fringing reef structure and growth models,” particularly on shallow gradient substrates fringing reefs may grow in complex ways and diverge significantly from the Darwin's classic simple model of seaward progradation from the shore. On more gently sloping coasts fringing reefs may initiate over a relatively broad area if suitable substrate is available, so that a diffuse “incipient reef” comprised initially of separate patch reefs may coalesce to form a more substantial fringing reef structure (Figure 1b). Chappell et al. (1983) suggested these models could accommodate many fringing reefs of the GBR, but they clearly have wider

application (as do a variety of other fringing reef growth models outlined in section “Fringing reef structure and growth models”).

The majority of fringing reefs can be broadly classified as one of the four main types on the basis of their coastal setting:

1. Headland/rocky shore-attached fringing reefs (Figure 2a).
2. Bayhead fringing reefs that develop in embayments and prograde out from the head of the bay (Figure 2b).
3. Beach base fringing reefs that develop along linear stretches of often sandy coasts (Figure 2c).
4. Nearshore shoals which can occur in all of the above coastal settings, but are not directly attached to the shoreline (Figure 2d). The water depth separating these reefs from the shore will be less than 10 m, satisfying the definition of a fringing reef, but they may become “true” fringing reefs if the coast progrades onto the leeward reef margin, as inferred at Yule Point, on the northern GBR (Bird, 1971).

This simple classification scheme requires little explanation. However, any particular fringing reef, or section of it, may display characteristics transitional between more than one class, both in space and through time. For example, at Paluma Shoals on the central GBR the northern shoal is attached to the shoreline by intertidal sand flats

and is a “beach base” fringing reef, but the southern shoal is presently separated from the shoreline and is a nearshore shoal (Figure 2d). It is also important to recognize that the terrestrial (and marine) influences affecting fringing reefs in each of these settings may differ, and will affect reef development. Drilling results show that many fringing reefs have accumulated over foundations of several different types (e.g., Hopley et al., 1978, 1983; Camoin et al., 1997), and establish that a basal reef rubble unit is common above the pre-reefal substrate. This suggests that once some fringing reefs have established fore reef talus (e.g., Tudhope and Scoffin, 1994) and/or detrital clasts washed to leeward (e.g., Easton and Olson, 1976; see Hopley et al., 2007) may accumulate and provide a substrate on which later reef growth may proceed. However, this process cannot proceed indefinitely, with fringing reefs prograding more slowly when the rate at which detrital basal deposits are formed or preserved is diminished. For example, the ages of fossil microatolls (see *Microatoll*) across the reef flats of bayhead fringing reefs on the GBR show that many rapidly prograded to fill most of the enclosing bays between around 6,500 and 2,000 years ago, but have accreted very little in the past few millennia (Smithers et al., 2006). This probably reflects two factors – the shutdown of vertical reef growth and sediment supply as a result of relative sea-level fall during the late Holocene, and reduced retention of

**Fringing Reefs, Figure 2** (a) Headland/rocky shore-attached fringing reef, Murray Island, Torres Strait; (b) bayhead fringing reef, Pioneer Bay, Orpheus Island, GBR; (c) narrow beach base fringing reef, Cape Tribulation, GBR; (d) nearshore shoal, Paluma Shoals, GBR.

sediments at the reef edge due to greater exposure to longshore currents at the mouth of the embayment, where ongoing seaward progradation is now constrained by the same processes that have limited substantial fringing reef development on the adjacent headlands.

A review of the available chronostratigraphic data available for fringing reefs indicates that most began to form soon after the sea inundated the substrate during the postglacial transgression, and that the bulk of most fringing reef frameworks were in place within a few thousand years (Kennedy and Woodroffe, 2002; Montaggioni, 2005; Hopley et al., 2007). Where later start-ups have occurred it is likely that the substrate is only recently available, due perhaps to shoreline movement or migration of shallow marine sediment deposits (Larcombe and Woolfe, 1999; Perry, 2005), and/or the environment is very marginal and reef growth is episodic. Although the details of why some apparently suitable substrates are not colonized by fringing reefs while some very marginal substrates are remain unknown, the rapidity with which corals have colonized most suitable coastal substrates and have developed fringing reefs has been observed at sites of recent volcanic activity (Umbgrove, 1930) and is demonstrated by the weight of radiometric dates from basal units in fringing reef cores (see *Radiocarbon ( $^{14}\text{C}$ ): Dating and Corals*). On this basis it would seem logical to suggest that substantial fringing reefs have probably already established at most sites that they are likely to.

#### Influence of terrestrial runoff, sediments and nutrients on fringing reefs

The environmental conditions required for coral growth are necessary prerequisites for fringing reef development, and where these conditions are not met or are marginal, fringing reefs will be absent or poorly developed. At a broad scale this is most markedly expressed on tropical coasts near major rivers where massive freshwater plumes and sediment flux have limited fringing reef development, such as in the western Atlantic south of around 5°N where the influence of the Amazon is felt, or adjacent to the Mekong, Niger, Congo, and Irrawaddy Rivers where fringing reefs are similarly lacking (Hopley, 1982). In addition to controlling fringing reef distribution, where reefs can grow, terrestrial runoff and associated sediments and nutrients may also affect fringing reef development and morphology.

Guilcher (1988) distinguished a range of fringing reef “subtypes” according to the extent of development of a deeper back-reef channel termed the “boat channel” (see *Boat Channel*) – a depression less than 10 m deep between the shore and the outer reef flat that is commonly used for small boat traffic on reef coasts. It was Guilcher’s view that the boat channel formed because coral growth was suppressed relative to that closer to the outer reef edge, most probably by freshwater, nutrients, and sediments shed from the adjacent landmass. Water may also be ponded over the backreef in moats (see *Moats*), but

moats form where the ebbing tide is held over the reef flat (see *Reef Flats*) rather than in depressions produced where upward reef growth is inhibited. Guilcher (1988) proposed that the simplest fringing reefs were shore-attached and lacked a boat channel, and developed where terrestrial impacts on reef growth were minimal, as occurs in semi-arid areas such as in the Red Sea. As discussed in section “Fringing reef growth and sea level,” this view is oversimplistic as it does not consider the influence of relative sea-level history. Fringing reefs with incipient boat channels comprise another subtype, with a shallow (<2 m deep) navigable channel behind the reef crest, with scattered live corals but generally only limited sediment accumulation indicative of minor terrestrial runoff. These reefs are common in the Gulf of Aqaba, but reefs from the Seychelles, Sri Lanka and Madagascar may also be included in this subtype (Guilcher, 1988). Fringing reefs with well-developed boat channels – several meters deeper than the reef flat and up to several hundred meters wide – can also be recognized, for example, at Lord Howe Island in the Tasman Sea (Figure 3), and along the southwest coast of Madagascar. Finally, the most complex subtype described by Guilcher (1988) is fringing reefs with multiple land-locked lagoons – which he attributes to the combination of a wide intertidal zone and macrotidal range.

The influence of the adjacent landmass on fringing reef growth is well demonstrated on the GBR where fringing reefs are the most common reef type (758 of 2,904 named reefs [26.1%]) but significant development on the mainland coast is restricted to the rocky shores of the Whitsunday region, and then intermittently north of Cairns (Hopley et al., 2007). Elsewhere, coastal sediment dynamics, high seasonal fluvial yields from large coastal catchments, and high inshore turbidity associated with wind-wave resuspension of the inshore sediment prism (Woolfe and Larcombe, 1999) inhibit fringing reef initiation and growth (Hopley et al., 2007). Fine sediments may be resuspended very quickly by waves – at Nelly Bay, Magnetic Island, wave-driven turbidity increases of three orders of magnitude up to 100 NTU (Nephelometer Turbidity Units) have been measured in an hour (Orpin et al., 2004) (see *Turbid Zone and Terrigenous Sediment-Influenced Reefs*). Most fringing reefs on the GBR (652 of 758 [86%]) occur on high islands offshore from the mainland, although fringing reef development can be poor on those closer inshore. Fringing reef development is also poor on larger high islands such as Hinchinbrook Island and Gloucester Island where runoff can be substantial, but some large high islands do support good fringing reefs and so other controls must also be involved (Hopley, 1982). Although fringing reefs are abundant on the GBR they are generally relatively small (mean <1 km<sup>2</sup>), and a significant number (213 of 758 [28.1%]) are defined as “incipient” – indicating that they lack extensive reef flat development (Figure 1b). Although substrate geometry and other factors can restrict fringing reef size, the generally limited dimensions and development may also reflect their vulnerability to episodic disturbances such as flood

**Fringing Reefs, Figure 3** Lord Howe Island, Tasman Sea.

plumes that can produce mass mortality events from which recovery can be very slow, thus stunting reef growth potential. Luxuriant reefs offshore of Mackay photographed in the late 1880s that were killed by a cyclone-generated flood plume in 1918 had recovered little by 1982 (Hopley, 1982).

Sediment and nutrient delivery to coastal waters where fringing reefs grow has been linked to the degradation of many fringing reefs (e.g., Punta Islotes, Costa Rica [Cortes et al., 1994]; Rodrigues [Naim et al., 2000]; Seychelles [Jennings et al., 2000]), with impacts arising due to smothering and burial, elevated turbidity with loss of photosynthetic capacity and energetic costs, and increased competitiveness of fleshy macroalgae and shifts from a coral to algal-dominated ecosystem (Umar et al., 1998; Fabricius, 2005). For some fringing reefs sediment related impacts may be natural; for example, periodic shifts in the position of river mouths may affect fringing reef growth and potential growth areas (Cortes et al., 1994), and at a larger scale, two catchments draining into the GBR exceed 130,000 km<sup>2</sup> in area, and the total catchment area draining into the GBR is nearly 425,000 km<sup>2</sup>, and thus for significant stretches of the coast large inputs of sediment and runoff are experienced periodically during natural floods (Neil et al., 2002).

However, there are clearly thresholds of sediment and nutrient exposure above which corals are unlikely to survive to establish fringing reefs of significant size. Nevertheless, it is crucial to recognize that corals can adapt to these pressures and that critical thresholds vary with location. On the GBR, high terrestrial runoff, into a relatively low-energy and protected lagoon, routinely exposes corals on inshore fringing reefs to ambient levels of turbidity and sedimentation known to stress and possibly kill those on other reefs (Pastorok and Bilyard, 1985; Hopley et al., 2007), and stratigraphic evidence confirms that many fringing reefs have always grown under naturally turbid

conditions (Smithers and Larcombe, 2003; Perry et al., 2008). Many corals on these reefs grow vigorously, and have adapted to these turbid conditions (Anthony, 2000, 2006). Paradoxically, however, the apparent vigor of reef corals does not appear to directly translate to continued reef accretion – most fringing and nearshore reefs have not added much to their structures for several thousand years (Smithers et al., 2006).

### Fringing reef growth and sea level

Holocene sea-level changes have been an important control on the development of all modern reefs (see *Sea Level Change and Its Effect on Reef Growth*), flooding substrates suitable for reef initiation and then providing the accommodation space into which fringing reefs may grow (see *Accommodation Space; Postglacial Transgression*). The timing of initiation is broadly governed by substrate depth, with deeper substrates flooded earliest and shallow substrates more recently. The amount of accommodation space available above any substrate depends on the rate of sea-level rise, the lag between inundation and initiation, and the rate of vertical reef accretion. These all vary from place to place. The timing of initiation and rates of vertical reef accretion are discussed in the following section on reef structure and growth models.

Geographic differences in the nature of Holocene sea-level changes related both to ocean volume and regional and local isostatic adjustments to the redistribution of mass (see *Glacio-Hydro Isostasy*) have produced different growth responses in fringing reefs, most of which reflect the balance between rates of vertical reef accretion and relative sea-level rise, the net result of which is available accommodation space. The range of reef responses is summarized in Figure 4 (modified from Woodroffe, 2002). Figure 4 presents sea-level change – reef growth scenarios that can explain some of the morphological

**Fringing Reefs, Figure 4** Fringing reef growth responses as a function of sea-level change (based on 5.11 Woodroffe).

differences between fringing reefs of the Indo-Pacific – where present sea level was generally reached around 6,000 years ago has since slowly fallen to present (see *Mid Holocene*) (Pirazzoli, 1991) – and the Caribbean, where sea level has risen to present at a decelerating rate, to reach its current position only recently (Lighty et al., 1982) (see *Western Atlantic/Caribbean, Coral Reefs*).

Reef flat morphology is the most conspicuous consequence of the varying sea-level histories experienced by fringing reefs in different locations. Throughout the Indo-Pacific fringing reefs with back-reef reef flats (see *Reef Flat*) that are dry at low tide are widespread, often but not always reflecting the late Holocene sea-level regression experienced in this region (see *Postglacial Transgression; Sea Level Change and Its Effect on Reef Growth*). In these locations the now emergent back reef formed when sea levels were higher in the mid-Holocene and the modern reef is confined at a lower level at the reef front (e.g., Chappell et al., 1983). In the Caribbean, where modern sea level has only recently been achieved (Lighty

et al., 1982), fringing reefs with shallowly submerged back reefs are more common. Adey (1978) speculated that the divergent back-reef morphologies were principally a function of sea-level history; he suggested that shallow lagoons developed on the Caribbean reefs where the more vigorously growing reef crest reached sea level before the back reef, confining a shallow lagoon over the back reef at low tides.

### Fringing reef structure and growth models

The growth histories of modern fringing reefs are documented by the materials and depositional fabrics preserved in their internal structures. Detailed stratigraphic and sedimentological investigations augmented by radiometric dating have enabled the growth histories of many fringing reefs to be interpreted, revealing details on age structure, past reef morphology, and the dominant processes of reef construction. Kennedy and Woodroffe (2002) reviewed the published literature on fringing reefs and

identified six generalized models of fringing reef development which are presented in Figure 5 and described below:

### Vertical accretion and progradation

Fringing reefs of this type typically initiated over a deeper substrate flooded earlier in the postglacial transgression at a point now nearer to the reef crest than the shore. Although vertical and lateral reef accretion is relatively slow and concentrated around the point of initiation for about 1,000 years, reef growth soon after spreads across

a broader area – mainly to leeward – and rapidly grows toward the surface, exhausting available accommodation space over most of the reef flat. The reef front vertically accretes at a more rapid rate than the backreef – probably due to poorer water quality, and seaward lateral progradation slows as the reef front moves into deeper water (Figure 5a).

This model of growth fits the pattern of fringing reef development established by two of the earliest but most detailed chronostratigraphic studies yet undertaken on

**Fringing Reefs, Figure 5** Fringing reef growth models: (a) vertical accretion and progradation; (b) progradation out from shore over rocky substrate; (c) progradation over terrigenous sediments; (d) pulsed progradation; (e) reef crest formation and backfill; (f) storm-reworked framework and infill; (g) vertical accretion and backshore widening; (h) coastal progradation onto backreef margin (Modified from Kennedy and Woodroffe, 2002; Smithers et al., 2006).

fringing reef structure – Easton and Olson's (1976) study of Hanauma Bay, Oahu, Hawaii (reef flat 90 m wide, 10 cores, 63 radiocarbon dates), and Macintyre and Glynn's (1976) study at Galeta Point, Panama (reef flat 200 m wide, 13 cores, 32 radiocarbon dates). At both reefs initiation occurred around 7,000 years ago – at Hanauma Bay over volcanic tuffs and basaltic sands, at Galeta Point over Miocene calcareous siltstones – and was dominated by massive corals. At both reefs, between 6,000 and 3,000 years ago, vertical accretion by rapidly growing coral frameworks took place, at Galeta Point dominated by *Acropora palmata*, which quickly masked any influence of the underlying topography (vertical accretion rates of between 1.3 and 10.8 mm year<sup>-1</sup> occurred during this phase). At Hanauma Bay, vertical accretion rates during this main phase of reef growth were slower, averaging around 2.9 mm year<sup>-1</sup>. After about 3,500 years BP at Hanauma Bay and 2,000 years BP at Galeta Point negligible vertical accretion occurred – with the reef at the former dominated by the coralline algae *Porolithon* and only scattered coral colonies, and the reef flat at Galeta Point now dominated by sea grass and *Halimeda* meadows. Grigg (1998) reports that the Hanauma Bay reef continues to prograde seaward at around 22 mm year<sup>-1</sup>. In contrast, despite its impressive growth between 6,000 and 3,000 years ago, Galeta Point fringing reef is now effectively senescent.

The similarity of reef growth evident at Hanauma Bay and Galeta Point is perhaps surprising given that they experienced different sea-level histories (see section “Fringing reef growth and sea level”). The dominance of *A. palmata* in the framework during the main phase of reef growth was interpreted by Macintyre and Glynn (1976) as evidence that Galeta Point was a keep-up reef able to keep pace with a sea level that rose at a decelerating rate to its present position. Easton and Olson (1976) also concluded that Hanauma Bay was a keep-up reef, but this interpretation has been challenged because they did not recognize evidence of higher sea level during the mid-Holocene (Grossman et al., 1998), and it is now generally agreed to be a catch-up rather than keep-up reef (Grigg, 1998).

On the GBR, Hayman Island is the only fringing reef for which data are available that loosely follows this model (Hopley et al., 1978). At Hayman Island the fringing reef developed over a gently sloping substrate of last interglacial limestone, now more than 1 km from the contemporary shoreline at a depth between –15 and –20 m, very soon after it was flooded by the transgression (the earliest dated coral above the substrate is 9,320 years BP). The interpretation is that original reef was outflanked by shoreline retreat and shoreline backstepping during the transgression, stranding it offshore as a catch-up reef. Once sea level stabilized in the mid-Holocene the reef caught up, and back-reef infilling and seaward progradation from the new shoreline combined to construct the reef flat. In this regard Hayman Island reef flat may also have some affinity to the reef crest and backfill model depicted in Figure 5e described further below (section “Reef crest and backfill”).

### Progradation out from shore over rocky substrate

Fringing reefs complying with this growth model initiate at the shoreline where they grow up to sea level and then prograde seaward (Figure 5b). This model of fringing reef development is most like the simple model conceived by Darwin (Figure 1a). However, detailed studies demonstrating that any particular reef has grown this way – over a hard bedrock shoreline are rare – Rees et al. (2006) inferred that the windward fringing reef at Lizard Island on the northern GBR grew directly over a granitic bedrock foundation and has prograded seaward, but from the three cores presented it is difficult to confidently determine the broader growth pattern. In Torres Strait, drilling reveals that reef initiation occurred close to shore at both Hammond and Yam Islands (Woodroffe et al., 2000), the former over a Pleistocene reef limestone at around 7,000 years ago and around 1,000 years later at Hammond Island, over a granite substrate but with significant mud deposition occurring during reef growth.

The northern section of the fringing reef at Iris Point, Orpheus Island, also on the GBR, rises over a rocky but unconsolidated foundation; drilling suggests the reef grows over a boulder beach (see *Boulder Beach*) comprised of corstones winnowed from the regolith. These boulders vary from 0.4 m to several meters *a*-axis length, and would be stable under normal conditions. At Iris Point reef initiation took place around 7,000 years ago and vertically accreted rapidly (4 mm year<sup>-1</sup>) to be constrained by sea level by 6,250 years ago, as indicated fossil microatoll ages (Hopley and Barnes, 1985) (see *Microatoll*). By 5,500 years BP the reef flat had begun to prograde seaward, and because sea levels were falling post highstand (Chappell et al., 1983), the reef flat was constrained at a lower level than the older reef flat to landward. Rates of seaward progradation at northern Iris Point have been estimated at between 50 and 500 mm year<sup>-1</sup>. Significantly, another transect at Iris Point located around 1,000 m to the south shows a different (younger) age structure and internal fabric, demonstrating the fact that a particular growth mode may be very localized, even within the same reef. The southern part of the Iris Point fringing reef has grown over detrital material shed from the northern section and distributed alongshore, and in contrast to the older section which is composed of 40–60% framework, the southern reef contains less than 20% *in situ* framework (Hopley and Barnes, 1985).

Although detailed chronostratigraphic studies of fringing reefs with this growth strategy are rare, there are many narrow fringing reefs attached to rocky headlands that appear to have formed in this way, at least at some stage of their evolution.

### Progradation over terrigenous sediments

This model of fringing reef growth is characterized by reefs developed over sedimentary structures including Pleistocene alluvial fans (e.g., Paluma Shoals, GBR [Smithers and Larcombe, 2003]), transgressionary sediment deposits

trapped in embayments (e.g., Pioneer Bay, Orpheus Island [Hopley et al., 1983]) leeward island spits (e.g., Rattlesnake Island, GBR [Hopley, 1982]), and deltaic gravels (e.g., Myall Reef, Cape Tribulation, GBR [Partain and Hopley, 1989]) (Figure 5c). Typically (but not exclusively) these reefs initiate near the shoreline in relatively shallow water and prograde seaward as vertical accommodation space is limited, often by late Holocene sea-level fall. In such cases, as the reef progrades into deeper water only the upper few meters of its internal structure may be distinctly reefal, with a shallow reef framework capping a detrital and often muddy deposit below. This is the case of many fringing reefs surrounding the high islands of the GBR and in Torres Strait (Woodroffe et al., 2000; Hopley et al., 2007), and this has also been documented for fringing reefs off Mozambique (Perry, 2005) and in South East Asia. Tudhope and Scoffin (1994) demonstrated that the fringing reef at Phuket, which is dominated by a *Porites* framework (see *Porites*), has prograded over mud by a process of block toppling at the reef front as sea level has fallen since the mid-Holocene.

### Pulsed progradation

This model includes fringing reefs developed by episodically building a new reef structure parallel to the existing reef front, and then backfilling the intervening space with unconsolidated reef sediments (Figure 5d). Antecedent topographic controls are inferred as a probable control of this accretion pattern, but other factors may also be involved. The fringing reef at Yam Island, Torres Strait has developed in this way, indicated by dated subsurface corals from cores and fossil microatolls across the reef flat (Woodroffe et al., 2000). A similar pattern of reef development is described at Mangaia in the Cook Islands where two separate reef crests occur over the reef flat – an older reef crest over the emergent inner reef flat and the younger lower reef crest to seaward; behind each lies a backreef filled with detrital sediment (Yonekura et al., 1988). Sea-level fall is proposed as the principal driving factor for this episodic accretion, with the first phase concluding around 4,000 years ago, and the younger reef crest forming 1.7 m below the first around 2,000 years later (Yonekura et al., 1988). At the resort reef on Dunk Island, GBR, two separate phases of reef development can also be identified, one between 7,000 and 4,500 years BP and another after 1,600 years. In this lower energy setting, reef growth in both phases occurred as massive colonies grew to sea level and inter-colony spaces were infilled with reef rubble and terrigenous sediment (Perry and Smithers, 2010).

### Reef crest and backfill

In this growth model the reef crest reaches sea level more rapidly than the backreef to form a shallow lagoon that is later infilled (Figure 5e). This mode of growth is inferred for fringing reefs in the West Indies where sea level has only recently been achieved (Adey, 1978; Kennedy and Woodroffe, 2002), but also appears relevant to fringing

reefs in areas where there is no evidence of higher Holocene sea levels or where reef growth rates have been slow so that fringing reefs have only recently been sea-level constrained. Coring from fringing reefs at Mauritius and the Seychelles in the Western Indian Ocean, for example, indicate growth histories of infill behind a reef crest that reached sea level first, forming a shallow backreef lagoon (Montaggioni and Faure, 1997; Braithwaite et al., 2000). Similarly, at Lord Howe Island, a high-latitude reef, the broad reef crest around 200 m wide reached sea level around 5,000 years ago forming backreef lagoon (around 2 km wide and averaging 1.5 m deep) that has been slowly infilling since (Kennedy and Woodroffe, 2000), and Kan et al. (1995) suggest the fringing reef at Minna Island, Japan has a comparable history, complying with this growth model.

### Storm-reworked framework and infill

This growth model occurs in storm affected settings, and involves the destruction and reworking of reef framework by episodic storms, between which detrital material may be stabilized and form the substrate for the next phase of reef construction by calcifying reef organisms (Figure 5f). This model has been argued to be applicable to the fringing reefs surrounding Grand Cayman (Blanchon and Jones, 1995; Blanchon et al., 1997); storms have been linked to fringing reef growth and morphology in the Seychelles (Braithwaite et al., 2000). An internal structure dominated by detrital carbonate clasts, often deposited in distinct units was interpreted as signifying the importance of episodic accretion events such as cyclones on normally low-energy inshore reefs on the GBR (Smithers and Larcombe, 2003; Perry and Smithers, 2006), and given the importance of detrital material in most fringing reef structures it is probable that this model will also fit other areas affected by episodic high-energy storms.

### Other models

The six models above are applicable to relatively stable and “typical” shorelines. Fringing reefs occur in other tectonic and physical settings where additional but less common modes of reef growth can occur. On tectonically rising or subsiding coastlines the effect is to reduce or increase the amount of accommodation space respectively. As discussed earlier, where accommodation space is limited – as may occur on uplifted coasts – progradation dominates, whereas subsidence at rates higher than vertical reef accretion provides increased accommodation space – and vertical accretion tends to dominate reef growth (see Figure 4). Cabioch et al.’s study (1999) of fringing reefs around Grand Terre, New Caledonia elegantly demonstrates these effects, with different parts of the coastline subsiding and uplifting at rapid and slow rates. Where subsidence is rapid, relatively thick Holocene reefs have developed, where subsidence is relatively slow, only thin Holocene reefs have developed, and where uplift has occurred Holocene reefs comprise only a thin

veneer over the seaward edge of a Pleistocene reefal substrate. Another mode of fringing reef development was described from China Reef, Japan, where a narrow fringing reef initiated on a narrow Pleistocene reef terrace at around  $-10$  m, approximately 7,000 years ago, kept up with sea-level rise to form a narrow reef flat that has increased in width not through seaward progradation, which is depth limited, but through scarp retreat of the backing cliff in this high energy location (Kan et al., 1995) (Figure 5g). In contrast, some fringing reefs may have begun as nearshore reefs that were not shore-attached, but coastal progradation has built the shoreline onto the leeward reef margins (Figure 5h) – this model was proposed for Yule Point Reef on the GBR, and may also apply to King Reef, located 200 km further south (Figure 6).

Although some variations exist due to differences in substrate depth, quality and the details of late Holocene sea-level history in particular, the general pattern of accretion history established for the GBR is broadly applicable to fringing reefs worldwide. Most fringing reefs on the GBR have accumulated a Holocene veneer of modest thickness, generally rising 5–10 m above their pre-Holocene foundations. Most reached sea level – or were within a few meters of it – between 7,000 and 5,000 years ago (Hopley et al., 2007) (and even in the Caribbean where modern sea level has only recently been reached, the bulk of many fringing reefs was emplaced over the same period). Vertical accretion rates of  $4\text{--}5\text{ mm year}^{-1}$  through this period are only marginally lower than the outer reefs (Figure 7). The most rapid growth is generally associated with catch-up phases on the GBR (and keep-up

phases in the Caribbean), with growth rates typically slowing in shallower water as accommodation space is reduced and hydrodynamic constraints associated with wave energy are experienced. Intrinsic and naturally reduced vertical accretion rates are common near the surface of reef cores from all over the GBR due to waves and other pressures (Davies and Hopley, 1983). However, higher rates are sustained to depths approaching 16 m at outer and mid-shelf reefs, but are restricted to a narrow depth window at  $\sim 4\text{--}8$  m below palaeosea-level on fringing reefs (Partain and Hopley, 1989). This possibly reflects the higher turbidity and sedimentation experienced at most fringing reefs compared to offshore reefs, and the reduced light-enhanced calcification at greater depths, especially in areas of higher tidal range.

Relatively little fringing reef development has occurred in the past few millennia, even where apparently healthy coral communities have occupied fringing reef slopes, and recent growth has mainly been limited to nearshore turbid-zone reefs initiating on newly exhumed substrates (Smithers et al., 2006). This age structure was established for many fringing reefs of the Central GBR by early research by Hopley (1982), and was confirmed as a broader regional trend by Chappell et al. (1983) who dated fossil microatolls across seaward sloping fringing reef flats through the Northern and Central GBR. Davies and Hopley (1983) noted that fringing reefs had a bimodal detrital accretion rate, with a lower range of  $1\text{--}5\text{ mm year}^{-1}$  associated with ambient conditions but a very rapid rate of up to  $15\text{ mm year}^{-1}$  attributed to rare high magnitude storm events. Rapid rates of vertical accretion associated with storms have been reported on fringing reefs in various

**Fringing Reefs, Figure 6** King Reef, Central GBR. Fringing reef initiated offshore with progradational coastline behind.

**Fringing Reefs, Figure 7** Fringing reef growth rates and sea-level constraint age on the GBR (Modified from Hopley et al., 2007).

locations around the world (e.g., Grand Cayman Island – Blanchon et al., 1997; Seychelles – Braithwaite et al., 2000). The importance of storm detritus versus *in situ* reef framework in fringing reef construction, and natural variability in both vertical and lateral rates of fringing reef growth are raising challenging questions about measuring and monitoring reef growth, destruction and condition to establish baselines in the face of projected environmental changes (e.g., Smithers et al., 2006).

### Fringing reef morphology and processes

Where fringing reefs have formed reef flats, their surface morphology is usually simple, comprising three main zones – a forereef, a reef crest, and a backreef. Fringing reef morphology can vary, however, over a single reef and from reef to reef, with the greatest complexity usually developed where the reef flat (see [Reef Flats](#)) includes sections formed during and after the mid-Holocene highstand (see section “Fringing reef growth and sea level”). Hopley and Barnes (1985) described seven geomorphological zones (see [Geomorphic Zonation](#)) on the northern section of the reef flat at Iris Point, Orpheus Island, GBR, the higher inner part of which reached sea level in the mid-Holocene (based on a 6,250 year old reef flat *Favid*). Only five zones were discriminated on the younger (near surface date: 3,780 years BP) southern section of the reef flat ([Figure 8](#)). Although the descriptions below are derived from a higher energy fringing reef on the GBR, the morphological zones discussed below may to varying degrees and combinations be found on many fringing reefs worldwide.

#### High water shingle and debris

An irregular ridge of mainly *Acropora* shingle to 10 cm length but also including other reefal debris, pumice and flotsam is deposited at the highest level of contemporary storm activity (see [Shingle Ridges](#)). This ridge can rise to over a meter in height, and usually has a steep seaward face. The lee side is often less abrupt, and can include small fans or splays. In more protected locations this zone may be replaced by a sandy beach, as occurs at nearby Pioneer Bay (Hopley et al., 1983).

#### Terrigenous boulder beach

Rhyolite and basalt boulders form a beach around 35 m wide that lies behind the reef flat. The lower boulder beach is cemented but the upper beach, which extends to the highest tidemark, is not. *In situ* corals indicative of a higher (~1 m) sea level in the mid-Holocene are attached to the boulder beach (Hopley and Barnes, 1985) in a manner comparable to that recently described at Dunk Island (Perry and Smithers, 2009). In other settings, a sandy beach, possibly with beach rock exposed, may replace the boulder beach (see [Beach Rock](#)).

#### Inner moat

A moated pool extends from the base of the boulder beach seaward to the shingle rampart (see [Moats; Moating](#)). At low tide water 0.3 m deep remains within the moated pool, >1 m above the open water low tide level. Corals including *Porites* and *Goniastrea* microatolls survive in this moat. A veneer of poorly sorted carbonate sediments floors much of the moat, with abundant rhodoliths (see [Rhodoliths](#)) accumulating at the landward edge. This zone is typical of fringing reef flats partly formed during higher mid-Holocene sea level, but can also occur where uplift has occurred or high-energy storms are common.

#### Shingle rampart

A shingle rampart to 0.3 m high and around 10 m wide was located at the seaward edge of the inner moat when Hopley and Barnes (1985) mapped the reef flat, but much of it has since been destroyed. This feature is formed when rubble is thrown onto the reef flat by storms, and similar features are common on other fringing reefs exposed to these events. Subtle bassett edges are sporadically preserved that document the former extent and position of the rampart at Iris Point (see [Bassett Edges; Shingle Ridges](#)).

#### Algal terraces

An algal pavement forms a relatively smooth feature that slopes down from the higher inner reef flat and shingle rampart to the lower outer living coral zone along most of the northern part of the reef flat at Iris Point. Crustose coralline algae (see [Algae, Coralline](#)) forms patches of this pavement, but it is mostly composed of *Acropora* shingle that has been stabilized with a filamentous turf algae (see [Algae, Turf](#)). Within this algal turf matting foraminiferans such as *Amphistegina*, *Calcarina*, and *Baculogypsina* are produced in great abundance (see [Foraminifera](#)). This feature is comparable with the algal-cemented pavements that are common on fringing reef flat across the Indo-Pacific.

#### Northern fossil microatolls

A pavement of coalesced fossil microatolls, some reaching 3 m in diameter, is located on the outer northern part of the reef flat at Iris Point. The tops of these microatolls are elevated ~0.8 m above their modern open water counterparts. There is no evidence that these microatolls have been moated, and they are therefore presumed to have formed at a higher sea level.

#### Amorphous southern reef flat

This zone is developed where the reef achieves its greatest width, and essentially consists of a relatively uniform, gently sloping surface of coral rubble bound by pink crustose coralline algae on its outer half and filamentous brown algae on the inner half. Radiocarbon dates indicate that this section of the reef flat was constructed after the mid-Holocene highstand. Hopley and Barnes (1985)

**Fringing Reefs, Figure 8** Iris Point fringing reef: (a) oblique photograph; (b) surface morphology; and (c) internal structure and chronostratigraphy (After Hopley and Barnes, 1985).

speculated that this possibly accounted for the morphological simplicity of this section of the reef flat.

### Outer living coral zone and reef slope

Live coral cover and biodiversity increases below mean low water springs on the outer reef flat. Soft corals (*Lobophyton*, *Sinularia*) and massive or head corals such as *Porites* and *Goniastrea* dominate at the rear of this zone, with *Acropora* becoming more abundant toward the reef crest. Patch reefs seaward of the crest are sporadically distributed along the reef front.

The physical processes operating of fringing reefs are covered in other entries and are not repeated here (see *Fringing Reef Circulation; Hydrodynamics of Coral Reef Ecosystems; Reef Flats; Reef Front Wave Energy; Wave Set-Up; Waves and Wave-Driven Currents*). It is more important to reemphasize that fringing reefs are exposed to particular processes due to their proximity to land, such as flood plumes (Devlin et al., 2001) and turbidity and sediment influx (Cortes et al., 1994; Wolanski et al., 2005), which may complicate the marine processes that structure reefs further offshore. Debate about the impacts of terrestrial exports on reef health is ongoing. It is, however, relevant to emphasize that many fringing reefs are (1) growing at their environmental extremes, and (2) are relatively old features at the “mature to senile end of the evolutionary spectrum” (see *Reef Classification by Hopley (1982)*). Although the pressures facing fringing reefs may have increased during recent times due to anthropogenic activities, it is critical to note that many fringing reef flats have been largely dead for thousands of years due to late Holocene sea-level fall (see section “Fringing reef growth and sea level”), and the net calcium carbonate productivity of most fringing reef reef-slope communities has been insufficient to enable significant lateral accretion for several thousand years (e.g., Smithers et al., 2006). The vulnerability of fringing reef flat communities, natural perturbations must be recognized when assessing the significance and causes of changes in reef flat community status; for example, reef flat coral communities surviving in moats at Holbourne Island, GBR suffered significant mortality when the confining rampart was breached by a cyclone in 1918 (Hopley and Isdale, 1977), lowering water levels by 40 cm, and as discussed in section “Fringing reefs and terrestrial influence” of this entry, natural movements in stream mouth position can directly impact on fringing reefs as documented at Punta Islotes, Costa Rica (Cortes et al., 1994).

### Summary

Fringing reefs are shore-attached and are exposed to a variety of pressures and processes related to this association that can affect their development. Although most fringing reefs are morphologically simple, their morphologies may become more complex where they incorporate reef flats formed at higher mid-Holocene sea levels, and where terrestrial inputs and processes affect them. The

apparent geomorphological simplicity of many fringing reefs masks development histories and internal structures that can be complex and diverse – fringing reefs develop over a range of foundations and are constructed of a variety of materials deposited in numerous arrangements (Figure 5). Of course, reefs are three-dimensional structures, and structural variation may occur within a single fringing reef. Although geographical variation exists due to differences in Holocene sea-level history and substrate availability, most fringing reefs experienced a period of active growth from 7,000 to 5,000 years ago when they produced most of their structure. On many fringing reefs living coral is now restricted to a narrow band near the seaward reef edge.

## FUNAFUTI ATOLL

Shigeru Ohde  
 University of the Ryukyus, Okinawa, Japan

## Synonyms

Ellice Island; The main island of Tuvalu

## Definition

An atoll of Tuvalu located in the tropical South Pacific.

## Introduction

Funafuti Atoll (8°31' S, 179°12' E) forms a part of the Tuvalu Group (formerly the Ellice Islands). It is a typical atoll composed of ~33 reef islands (a total land area of 2.4 km<sup>2</sup>) and a lagoon of ~18-km diameter (275 km<sup>2</sup>). The islands are formed from fossil coral limestone and calcareous marine carbonates, particularly larger foraminifera. The lagoon has three main deep channels. Additional lagoon/ocean water interchange takes place over the reef rim, especially on the western side where the islets are small and widely separated. A total of 36 species of coral were recorded in 1983 and the blue coral *Heliopora coerulea* was abundant on the western rim (Buckley, 1985). A variety of corals occur on the reef slope and reef buttresses including *Acropora*, *Pocillopora*, *Montipora*, *Millepora*, *Acanthastrea*, *Favia*, etc. Over 200 fish species and 400 mollusks have been identified from the lagoon (UNEP, 1988). In the shallow lagoon, larger foraminifera are the dominant component of sand and gravel, while *Halimeda* replaces the foraminifera in deeper water (Collen and Garton, 2004). There are abundant coral reef fauna in the lagoon and on the reef.

The capital of Tuvalu is located on Fongafale islet, the main island of the atoll. Four thousand four hundred and ninety two people live on Funafuti Atoll (2002 Census). The total national population of Tuvalu is 11,126 in 2007 (<http://www.spc.int/prism/country/tv/stats/>). While tropical cyclones (recorded in 1891, 1958, 1972, and 1997) have destroyed many buildings on Funafuti, they have also played a significant role in land formation by re-sedimentation of submarine carbonates (Maragos et al., 1973). Recently, floods on Funafuti, especially on Fongafale islet during spring high tides were possibly associated with sea-level rise caused by global warming (Patel, 2006). More than 100 years ago, the Royal Society of London mounted an expedition to Funafuti Atoll to test Darwin's theory of the formation of coral atolls (Royal Society, 1904). The IUCN Conservation Monitoring Centre book, *Coral Reefs of the World*, provides useful information of Funafuti (UNEP, 1988). Also, over 1,000 references concerning the geology and biology of Tuvalu are indexed and annotated by Rodgers and Cantrell (1988).

## The Royal Society Coral Reef Expeditions

In 1896–1898, under the leadership of Professor Tannant Edgeworth David (Sydney University), the Royal Society drilled a 339-m drill hole on Funafuti Atoll to carry out the experiment desired by Darwin to interpret the origin and history of coral reefs (Darwin, 1842; The Royal Society, 1904; Grimsdale, 1952). But, the drilling did not reach the base of the atoll; however, it showed clearly that shallow water limestone over such a thickness must have been accompanied by a subsidence. Subsequent, but much later drilling by the U.S.G.S. at Eniwetok and Bikini Atolls in the 1950s proved finally that at least some atolls also had volcanic basements (Emery et al., 1954; Ladd and Schlanger, 1960). Over a century after the Funafuti

Expedition, selected samples from the 339-m-long drill core (preserved at the Natural History Museum) have been dated using high-precision radiocarbon and Sr isotope measurements (Ohde et al., 2002). From the radiocarbon dating, the top 26.4 m of the core records the history of sea-level rise during the last 8,000 years. For the previous two million years, however, only the recent use of high-precision Sr isotopic data have made it possible to provide records of the Quaternary sea-level history preserved in the atoll carbonates. During the past 1.5 million years, more than 150 m of reef-lagoonal carbonate was deposited through an interaction between glacial/interglacial sea-level changes and plate subsidence. Sections of dolomite in the lower core (196–339 m) were formed through diagenetic alteration between one and two million years ago, possibly resulting from seawater percolation. The atoll sequence reflects the interaction between carbonate sedimentation, tectonic subsidence, and eustatic sea-level change, and potentially provides a two million-year record of environmental change.

## Holocene reef growth at Funafuti

Radiocarbon dating of fossil corals provides information on Holocene reef history at Funafuti. Three shallow borings were carried out on the reef-flat of Fongafale (Royal Society, 1904). The top 26.4 m of the main boring is mainly composed of corals, including the soft coral *Sinularia* sp. (Table 1). The predominant corals belong to the genera *Millepora*, *Heliopora*, *Pocillopora*, *Favia*, *Porites*, and *Montipora*. Nine coral aragonite coral samples from the core top were dated by the accelerator mass spectrometry (AMS) radiocarbon method and calibrated (Ohde et al., 2002). Table 1 shows that the Holocene-Pleistocene boundary is situated at a depth between 26.4 and 27.4 m. Using the cores preserved at the Natural

<sup>a</sup>The top of the core is at 0-m altitude and depths correspond to distances below surface

<sup>b</sup>Radiocarbon dating calibrated by INTCAL98

<sup>c</sup>Determined by <sup>226</sup>Ra/<sup>238</sup>U method

History Museum, it was observed that a change of carbonate textures occurred at 26.4 m – from a fossil reef above to strongly cemented facies below. The reef has grown upward from 8,130 to ~2,500 years BP at a growth rate of 4.73 mm/year ( $26,400/[8,130-2,550]$ ), much higher than those recorded at Enewetak, Mururoa, and the Cook Islands, but similar to that of Barbados (Fairbanks et al., 1989). The reef growth of 26.4 m reflects the infill of accommodation space for new reef growth made by the glacial stage erosion of the last interglacial stage 5e, continuing subsidence and rising Holocene sea level.

### Reef Island formation: higher sea-level or storm impacts?

The Royal Society (1904) reported on the island morphology of Funafuti Atoll, declaring that the island ridges (~2 m altitude) were composed of unconsolidated coral rubble and associated carbonate sand and corals in growth position on top of reef flat. Such observations have been used to infer that parts of the islets were formed during a mid-Holocene highstand and a subsequent fall to modern sea level (Schofield, 1977; Dickinson, 1999). However, it is undeniable that Funafuti Atoll is low lying and vulnerable to tropical storms (Maragos et al., 1973). Unconsolidated materials on Funafuti islets may therefore represent amalgamated rubble sheets deposited by storm-wave washover of the islets and episodic formation of rubble ridges on the reef platform (Dickison, 1999). Radiocarbon dating of reef blocks (probable storm deposits) together with historical records have been used to compile a history of large tropical storms in Funafuti Atoll, indicating major storms occurred in 2,000, 1,600, 1,450, 1,050, and 600 conventional radiocarbon years ago (McLean, 1992, 2004). In October 1972, a huge rubble rampart 18-km long (~10% of the land area of the atoll) was suddenly formed at Funafuti during cyclone Bebe, the material derived from deeper water offshore. Tropical cyclones therefore play potentially important role in the land formation of atolls such as Funafuti (Maragos et al., 1973). Radiocarbon dating of cores and surface samples (Schofield, 1977) show that the land area was estimated to form ~2,000–1,000 years ago on the reef flat when the sea level reached modern level (Schofield, 1977; Yamano et al., 2007). Prehistoric human settlement of Funafuti was also assumed to be much more recent than other traditionally populated islands like Majuro Atoll, the Marshall Islands (Yamano et al., 2007). Low altitude atolls are in future at risk from coastal damage caused by tropical storms and sea-level rise associated with predicted global warming by anthropogenic activities (Woodroffe, 2008). Cyclone Bebe was called as the strongest cyclone these 100 years (Baines et al., 1974). However, the lowest barometric pressure of 954 mb recorded during the storm (Maragos et al., 1973) is not too low compared to typhoons occurring in the tropical western-north Pacific. Therefore, Funafuti is in future at risk of flooding and damage by projected stronger cyclones.

### Funafuti and predicted sea-level rise

Recently, widespread floods in the interior of Fongafale islet on Funafuti have frequently occurred during spring high tides. Patel (2006) reported that Funafuti people feel the floods are getting worse possibly associated with sea-level rise caused by global warming. The potentially huge impact of sea-level rise on the people of Funafuti should be evaluated from the best estimate of sea-level change and its associated uncertainty from the available data. Hunter (2002), using two sets of data, one from the University of Hawaii Sea Level Center and the other from the Australian National Tidal Facility, predicted a rise of 0.8 ( $\pm 1.9$ ) mm/year. Rejecting data affected by Southern Oscillation events, Hunter predicted a rise of 0.4 and 2 mm/year at a 68% probability level. This would represent a rise of 4–20 cm in 100 years and could significantly increase the frequency and depth of saltwater flooding and accelerate coastal erosion, threaten the local food and housing, and could make the country simply uninhabitable. Many Tuvaluans may become environmental refugees when the island is drowned by the sea-level rise (Mortreux and Barnett, 2009). Even greater difficulties will arise as a consequence of rising sea levels and increased intensity and/or frequency of high-energy cyclonic events. Both will impact an atoll ecosystems much changed by anthropogenic processes (e.g., construction of an airstrip over original mangroves).

In conclusion, low-lying islands such as Funafuti are, in future, at risk of coastal damage including erosion, inundation, coral bleaching, changes in fishery resources, and agricultural productivity (Woodroffe, 2008; Mortreux and Barnett, 2009). Such risks are likely derived from changes in the island ecosystems on which Funafuti people depend for their livelihoods and cultures. Short-term scientific observations show little evidence of sea-level rise in Funafuti (Patel, 2006), but the Government of Tuvalu has argued that there is a visual evidence of sea-level rise, through such consequences as increased erosion, flooding, and salinity (Connell, 2003) and that Funafuti Atoll is in future at risk from coastal damage caused by the sea-level rise associated with predicted global warming by anthropogenic activities.

### Summary

Funafuti Atoll was the site of the Royal Society Coral Reef Expeditions in 1896–1898. The 339-m core was drilled into the atoll (at 0-m altitude) on Fongafale islet to carry out the experiment outlined by Charles Darwin to elucidate the origin and history of atoll formation. From the radiocarbon dating, the top 26.4 m of the core records the history of sea-level rise during the last 8,000 years. Sr isotope stratigraphy of the core indicates that during the past 1.5 million years, more than 150 m of reef-lagoonal carbonate was deposited through interaction between sea-level change and plate subsidence. Dolomite in the lower core (196–340 m) was formed through diagenesis between one and two million years ago. Radiocarbon dates of the core-top

together with surface fossil corals suggest that the land areas in the atoll were formed on the reef flat about 2,000 to 1,000 years ago. In 1972, cyclone Bebe struck Funafuti and showed tropical storms also play a significant role in the land formation of the atoll. Recently, floods have often occurred on Fongafale islet during spring high tides. In future, Funafuti will suffer the ravages of both high-energy events and rising sea levels.

## GARDINER, JOHN STANLEY (1872–1946)

---

Barbara E. Brown  
University of Newcastle upon Tyne, Durham, UK

### Definition

An eminent British zoologist who is primarily recognized for his early work on reefs throughout the Indian Ocean but who was also a major influence on the 1928–1929 Great Barrier Reef Expedition from its inception through to review of its resultant publications.

Professor Stanley Gardiner was best known for his extensive expeditions into the Indian Ocean to study the flora and fauna of coral reefs and islands in the early 1900s. As a young man, he joined the Royal Society Expedition to Funafuti in the Ellice Islands in 1896 to assist the deep boring of an atoll and test the “subsidence theory” of reef origin proposed by Charles Darwin. On this trip, he also visited nearby Rotuma and Fiji carrying out preliminary experiments on coral nutrition and growth, the results of which made him one of the first scientists to question the role of coral symbiotic algae in these processes. During 1899–1900, 1905, and 1908, Gardiner undertook several expeditions into the Indian Ocean working in the Laccadives, Maldives, Chagos Archipelago, Farquhar, Providence, St. Pierre, and Mauritius. He was one of first scientists to provide detailed descriptions of the reefs of the Indian Ocean together with taxonomic details of their constituent corals as well as comments on their form and possible modes of origin.

Less well known is the fact that he was a key figure in the instigation of the 1928–1929 Great Barrier Reef Expedition; in the funding and appointment of C.M. Yonge as

its leader; in the development of the scientific programme; and in evaluation of scientific papers which resulted from the expedition’s activities.

Gardiner was elected to the Fellowship of the Royal Society of London in 1908 and in 1909 became Professor of Zoology at Cambridge. In 1929, he was awarded the Agassiz Medal of the National Academy of Sciences of the United States and while in the country he delivered a series of lectures on coral reefs at the Lowell Institute in Boston which were published a year later in a book entitled “Coral reefs and atolls.” In 1936, he was awarded the Linnean Medal of the Linnean Society and in 1945 the Darwin Medal of the Royal Society of London. Throughout his life, he promoted coral reef interests both within his Department and abroad. At home, he provided a laboratory for fellow reef scientists such as R.B. Seymour Sewell and Cyril Crossland while personally supervising George Matthai’s anatomical treatise on soft tissues of reef corals. He entertained overseas visitors in Cambridge and during his and his student’s visits to the United States engaged actively with Thomas Wayland Vaughan, Alfred Goldsborough Mayer, and Alexander Agassiz. His legacy to reef science was much more than descriptive studies from the Indian Ocean and included scientific and administrative steerage of the Great Barrier Reef Expedition which set the scene for a new phase in the development of reef science in the twentieth century.

## GENERAL EVOLUTION OF CARBONATE REEFS

Rachel Wood

University of Edinburgh, Edinburgh, UK

### Introduction

While modern coral reefs are sites of high biodiversity forming impressive wave-resistant structures in clear tropical waters, many other organisms are known to form diverse types of reefs in temperate, low-energy settings or in deep waters.

Reefs have developed on Earth for over 3.5 billion years, and a tremendous diversity of communities of skeletal and nonskeletal metazoans, plants, algae, and microbes as well as inorganic calcium carbonate precipitation processes have contributed to their formation during this time. Reefs have shown zonation in response to environmental gradients from their inception, and metazoan reefs have been differentiated into open surface and cryptic reef communities for their entire ~550 million-year history (Wood et al., 2002).

Ancient reefs were biologically constructed reliefs that grew on the seafloor that are now expressed as massive bodies of calcium carbonate rock surrounded by bedded strata (Figures 1 and 2). Some formed small isolated structures; others became sufficiently large so as to influence the regional oceanographic and sedimentological environment. However, as sites of in situ biological growth, they often

record abundant palaeoecological information lost from other types of communities, as well as data that can be used to unravel changing climate and oceanography over evolutionary timescales.

Given the diversity of ancient reefs and settings, a strict uniformitarian approach to understanding reef evolution has limited utility. Indeed, for decades there has been an ongoing debate as to what constitutes an ancient reef (see James, 1983; Fagerstrom, 1987; Geldsetzer et al., 1988; Wood, 1999; Stanley, 2001 for summaries). A general term often used for ancient reefs with no connotations as to processes of formation, size, or shape is carbonate buildup.

Many ancient reefs had fundamentally different ecological and environmental demands compared to modern coral reefs. But all reefs, regardless of the organisms that form them or where they grow, are controlled by factors that enable the biological occupation of space on the seafloor.

All reefs show the recurring processes of (1) in situ biological fixation of carbonate by organic assemblages of microbes, algae, and metazoans, (2) development of internal cavity systems during growth, (3) synsedimentary lithification, and (4) bioerosion (Figure 2). Reef evolution has recently been reviewed by James and Wood (2010), and the following review has been based in part upon this work.

### Biological fixation of carbonate

Calcareous metazoans, algae, and microbes can either individually or in combination form a reef. The relative importance and abundance of each has changed through geologic time, leading to the wide array of ancient reef fabrics present in the geological record.

### Calcareous metazoans

All invertebrate taxa of calcareous metazoans have formed reefs at some stage in the past, but the most important groups are sponges, corals, bryozoans, and bivalves. Reef metazoans are often colonial or clonal and are capable of

surviving and regrowing or even multiplying after damage to their living tissues. All are obligate calcifiers in that the organism controls biomineralization.

Reef calcareous metazoans can be either heterotrophs or mixotrophs. Heterotrophs consume other organisms whereas mixotrophs are heterotrophs that also contain symbiotic microorganisms, generally photosynthetic cyanobacteria or single-celled algae.

Sponges including hexactinellids with siliceous spicules alone and those with calcareous skeletons were major reef builders in the past. Calcified sponges belong to several different groups including calcareans, demosponges, stromatoporoids (a group of sponges of probably mixed affinity that are distantly related to various modern calcified sponges), archaeocyaths, and chaetetids. Corals comprise both tabulates and rugosans from the Cambrian/Ordovician to the end Permian and scleractinians from the mid-Triassic onward. The other important organisms are bryozoans that, even though relatively small and delicate, are critical elements of many reefs and often act as scaffolds between which in situ microbially induced lime mud (micrite) can form and cements precipitate.

Although we cannot be certain about the physiological tolerances of many ancient fossil reef builders, some generalities are possible. In contrast to those organisms that contained phototrophic symbionts, heterotrophs would have been limited by the availability of light and nutrients. On the basis of isotopic (Stanley and Swart, 1995), and growth-form evidence, scleractinian corals probably possessed zooxanthellae by the late Triassic. Tabulate corals were a diverse group of organisms and it is not clear whether they contained similar symbionts. Rudist bivalves formed low-relief aggregations and were massive producers of sediment in the Cretaceous, but some of the most important groups did not appear to have symbionts (Steuber, 1999). Fossil sponges, both spiculate and soft bodied, and calcified sponges (such as stromatoporoids and archaeocyaths) are poorly understood and their association with photosymbionts is uncertain (Wood, 1999).

#### Calcareous algae

Calcareous algae, both red (coralline and squamaracean) and green (codiacean and udoteacean), are obligate

calcifiers. They can form reefs as well as binding and stabilizing reef frameworks being prolific producers of sediment. Such algae probably occupied these niches in the past. Calcareous algae have been part of the carbonate factory since the Ordovician but were not significant in reef communities until the early Carboniferous (Mississippian). Phylloid (leaf-like) algae were conspicuous reef builders in the late Palaeozoic.

### Microbes

Microbes are highly diverse single-celled prokaryotes and eukaryotes. Carbonate precipitation associated with them can be inferred by the presence of often encrusting microcrystalline micrite (lime mud) with peloidal, clotted or laminated fabrics, or by calcified microbial sheaths (calcimicrobes).

Microbes are non-obligate calcifiers in that they induce carbonate precipitation by their metabolic processes or postmortem chemistry: they are incapable of calcification under unfavorable conditions such as low carbonate saturation. The attributes of microbial textures are therefore thought to depend upon seawater carbonate saturation and postmortem preservation.

Calcification often takes place associated with a biofilm consisting of layers of organic matter (EPS – extracellular polysaccharide) that contains a variety of living and dead microbial communities within a matrix of degrading organic matter and mucilage. The precipitated microcrystalline micrite is sometimes called automicrite because it is produced in-place, generally on a substrate, and it can be an important binding or cementing agent.

It is also possible that some micrite formation in reefs relies mainly on early diagenetic organomineralization processes to aid calcite nucleation on dead organic matter, particularly via molecules derived from decayed sponges. The presence of abundant, reactive  $\text{Ca}^{2+}$ -binding fulvic acids have been confirmed in well-preserved Cretaceous mud mounds and modern coral reef caves.

Automicrite is the main constructor of layered stromatolites and clotted thrombolites. Stromatolites, composed of automicrite and symsedimentary cement, were the only reef builders throughout the Precambrian and were augmented by thrombolites and calcimicrobes in the Neoproterozoic. They have continued to be a variable contributor to reefs throughout the Phanerozoic. Calcimicrobes, once established in the Neoproterozoic, have continued to be a significant and sometimes dominant element of reefs throughout the Phanerozoic, particularly the Palaeozoic. Whereas automicrite is essentially an encrusting or binding element in most reefs, often within cavities, it may nevertheless contribute substantially to the reef rock volume.

The most common calcimicrobes are tubular (*Girvanella*, *Rothpletzella*), subspherical (*Renalcis*), or branching (*Epiphyton*). They are generally interpreted as sheaths of bacteria that have undergone variably taphonomic alteration. Many other similar structures of

complex affinity such as the Mesozoic *Tubiphytes* (probably a foraminifer–cyanobacteria association) have also been placed in this category. Calcimicrobes were also important sediment producers.

### Internal cavity systems

Much of most modern and ancient reefs are void space as metazoan-algal-microbe growth geometries often produce interconnected cavities, even in those reefs almost wholly composed of mud. These cavities are often shaded from light and suffer less predation or grazing and reduced wave energy compared to the open reef surface. Cavities are often populated by cryptic organisms that encrust walls and hang down from ceilings. They range from photic organisms near the openings to relatively fragile heterotrophs in the dark, lightless interiors. Automicrite often preferentially coats inner surfaces of cavities and encrusts the cryptic community. Cavities are also sites of fine-grained sediment accumulation, material composed of skeletal debris and mud that forms a geopetal internal sediment fill. Reef cavities first appeared in the Neoproterozoic coincident with calcimicrobes and thrombolites. Thereafter, they were a significant element of most reefs.

### Symsedimentary lithification

Most reefs are lithified immediately below the living surface by a variety of calcareous precipitates. Much of such cement is microcrystalline but other cements are spectacular, growing as millimeter or centimeter-sized crystal arrays from the walls and ceilings of cavities or between sediment grains. Such cements not only confer rigidity to reefs but also occlude much original pore space.

The location of the reef determines the amount of cementation. Platform-margin and down-slope reefs usually contain marine cements, particularly in high-energy areas, whereas lagoonal or inner-ramp reefs rarely do and so may be unlithified.

Symsedimentary cementation is an attribute of reefs of all ages but the type and mineralogy is controlled in part by changing seawater chemistry. The most intensive ancient cementation documented is found in Precambrian reefs, where some are volumetrically dominated by cements. The amount of crystalline cement in reefs decreases with the appearance of calcareous organisms in the Cambrian and then again following the evolution of calcareous plankton in the Jurassic: Many Palaeozoic reefs contain conspicuously more symsedimentary cement than Jurassic and younger examples.

### Bioerosion and predation

Living calcareous reef builders and reef rock are grazed upon by a variety of bioeroders, particularly limpets, echinoids, and fish that not only consume soft parts but also remove reef carbonate, which is reduced to fine sediment. Although present in the Palaeozoic, this component of in-place reef removal, bioerosion, and sediment production

began in earnest in the Mesozoic and has increased dramatically ever since (see entry *Bioerosion*).

### Geologic history of reefs

The Phanerozoic witnessed major turnovers of reef biotas, mass and minor extinction events, and profound changes in the chemistry of seawater. The evolving history of reefs has been reviewed extensively by Fagerstrom (1987), Wood (1999), Stanley (2001), Kiessling et al. (2002), and James and Wood (2010), and is summarized in Figure 3.

Reefs have broadly evolved from dense, stromatolite-dominated reefs of the Archean, with the appearance of thrombolites and calcimicrobes in the Neoproterozoic, forming the first reef cavities, to the successive rise of various skeletal metazoans from the earliest Phanerozoic onward.

During geological periods when large calcareous skeletal and microbial structures were common, reefs grew as fringing reefs landward, as patch reefs across platforms, and as barrier reefs along platform margins. Coeval mounds developed in either quiet water settings across the platform, or on ramps, or on the slope.

The formation of large, shallow-water, flat-topped platforms coincide with the periods of skeletal reef development because skeletal reefs are characterized by well-cemented carbonate buttresses along their seaward margin. These ramparts absorbed waves and swells, thus allowing more tranquil, protected lagoonal facies to develop across the platform interiors. When skeletal reefs were absent, carbonate ramps were the norm, where reef mounds and mud mounds were the only buildups, which either grew leeward of sand shoals or more commonly on deep-water ramps and slopes.

The great diversity of ancient reefs present a continuum of shared ecologies and sedimentary characteristics, but they can be divided into the broad end members of (1) skeletal reefs, (2) skeletal–microbial reefs, (3) microbial reefs, and (4) mud mounds (James and Wood, 2010; Figure 4).

### Skeletal reefs

#### *Shallow reefs*

Skeletal, shallow reefs, where skeletons dominate most of the rock volume, are restricted in geologic time to the (1) middle Ordovician to late Devonian, (2) late Jurassic, and (3) Cenozoic.

Although symsedimentary cements, microbes, and automicrite were present, they are usually of subsidiary importance, except during the intervals of the Palaeozoic. Internal cavities, which may comprise as much as 30% of the reef volume, can be sites of diverse cryptic communities, calcimicrobial growth, and internal sediment. Automicrite is present on, around, and between skeletons. Symsedimentary cement can be spectacular, with the largest amounts found in the reefs at the platform margin. Such reefs were built by calcified sponges (stromatoporoids), tabulate corals, or scleractinian corals.

These reefs, with their large skeletons and relatively rapid growth rates, are amongst the most extensive in the

rock record. Diversity is lowest in reef crest and deep-water environments, with both environments favoring sheet-like skeletal morphologies. The highest diversity of skeletons and shapes, and therefore rock types, occur at intermediate depths.

Growth forms and skeletal diversity are strongly controlled by hydrodynamic energy. Unlike modern corals, Palaeozoic stromatoporoid sponges and tabulate corals, even though they often grew as laminar forms, sat on or were anchored within the sediment (Figure 5). Large, tabular forms that were solidly rooted in the sediment inhabited high-energy zones such as the reef crest, but since stromatoporoids did not typically have an encrusting habit, it is doubtful that they were successful builders in the surf zone. Tabular stromatoporoids, locally bound together by calcimicrobes, automicrite, or cement, are also known to have occurred in energetic waters. Domal, bulbous, and dendroid forms occupied quiet water zones, either below wave base or in sheltered areas of the back reef and the lagoon (such as delicate stick-like amphiporoids). These skeletons were locally reworked during storms and redeposited as rubble units associated with peritidal settings.

#### *Deep-water skeletal reefs*

Today, deep-water skeletal reefs grow worldwide in water depths of between 250 and 1,500 m, where temperatures range from 4°C to 12°C (Freiwald and Roberts, 2005). They are constructed by scleractinian corals that lack photosymbionts, especially the branching form *Lophelia pertusa*. These reefs are muddy and unlithified and range up to 5 km long and 40 m high, with generally steep sides up to 160 m thick. Many are located in areas of elevated nutrients such as oceanic fronts or upwelling; others are sited on the top of cold hydrocarbon seeps.

Cold-seep reefs are part of a lineage of similar structures that extends back to the Silurian, but there are very few corals from methane seep communities older than the late Eocene. The rock record of such skeletal reefs is not extensive. The oldest known is Triassic, but they are not numerous until the Cenozoic, where an especially good record exists in north-west Europe and the Mediterranean region. Pre-Cenozoic deep-water reefs seem to be either skeletal–microbial mounds or mud mounds.

### Mixed skeletal–microbial reefs

Many ancient reefs bear two important constituents: small or delicate skeletal metazoans that are either heterotrophs or autotrophs (e.g., phylloid algae) and a microbial component of calcimicrobes or inferred microbialite (Webb, 1996; Wood, 1999). These structures with a mixed consortium of organisms are unlike most modern skeletal reefs and have been called reef mounds or biogenic mounds (James and Bourque, 1992). Such reefs often contain extensive framework cavities, with their own distinctive cryptic biotas and abundant symsedimentary cements (Figure 6b).

**General Evolution of Carbonate Reefs, Figure 3** Reefs through time, illustrating periods when skeletal, skeletal-microbial reefs, and mud mounds were important. Numbers indicate different associations of reef- and mound-building biota. Arrows – signal major extinction events. \* – scale change. (From James and Wood, 2010.)

Autotroph-microbial or heterotrophic-microbial communities dominated ancient mixed reefs in shallow waters of the photic zone. No direct modern analogs are known for either of these systems.

#### *Autotroph dominated*

Ancient examples of mixed autotroph reefs include Pennsylvanian to early Permian phylloid algal mounds. These algae are probably of mixed affinities and grew as laminar,

**General Evolution of Carbonate Reefs, Figure 4** A modified classification to describe reef carbonates. (From James and Wood, 2010, after Embry and Klovan, 1971.)

cup-, bowl-, or upright leaf-like forms that may have been encrusted by automicrite. Such reefs are usually low-relief isolated structures, appear to have grown in shallow waters, and are often associated with grainy sediments that indicate growth under fairly energetic conditions with extensive flanking beds. These mounds were typically the source of significant skeletal debris that formed extensive flank beds. *Halimeda* mounds have been reported from the late Miocene and may have been stabilized by the rapid lithification of micrite and microbial crusts (Martín et al., 1997).

#### *Heterotroph dominated*

Heterotroph reefs are common in the ancient record. Lower Cambrian reefs occur as small isolated mounds, consisting of archaeocyath sponges and calcimicrobes, particularly *Renalcis* and *Epiphyton* (Figure 7a and b). Lower Ordovician reefs were likewise dominated by calcimicrobes, microbialite and, locally, corals.

Some back-reef shallow-water Frasnian (late Devonian) reefs exhibit large skeletal metazoans (particularly stromatopore sponges and subsidiary corals), as well

as extensive fenestral microbialite and calcimicrobes, both as free-standing mounds and as secondary encrustations within cryptic habitats (Figures 5b and 6a).

Shallow-water Lower Carboniferous (Mississippian) reefs are formed by endemic communities composed of laminated microbial mounds with a rich encrusting open surface and cryptic fauna dominated by algae, bryozoans, corals, and sponges (Mundy, 1994; Webb, 1994; Ahr et al., 2003).

The mid-to-late Permian is characterized by extensive fringing reefs with a well-developed zonation. They consist in part of a primary framework of frondose bryozoans and calcified sponges (many of whom were cavity dwellers) that were bound by extensive crusts of laminated automicrite (Figure 6b). *Tubiphytes* is common, together with various encrusting algae including *Archeolithoporella*. Volumetrically, many of these reefs were dominated by sediment and syndimentary cement, or automicrite. Such successions are inferred to have formed within open cavity systems with freely circulating seawater, in response to decreasing light and energy conditions as the reef was progressively buried. Upper Jurassic

**General Evolution of Carbonate Reefs, Figure 5** (a) Large stromatoporoid sponge, growing over soft sediment. (b) Reconstruction of back-reef community, Late Devonian (Frasnian) Windjana Gorge, Canning Basin, Western Australia. 1. Stromatolites, 2. Domal stromatoporoid, 3. foliaceous stromatoporoid, 4. *Renalcis*, 5. fibrous cement, 6. internal sediment, 7. platy stromatoporoid, 8. crinoids, 9. branching stromatoporoid, 10. laminar stromatoporoid, 11. encrusting stromatoporoid, 12. microbialite, 13. clastic sediment, 14. gastropods, 15. Oncolites. (From Wood, 1999; Copyright J. Sibbick.)

shallow-water reefs were dominated by hexactinellid and lithistid spiculate sponges, coated by automicrite and thrombolites, and encrusted by a variety of biota.

#### Deep-water skeletal-microbial reefs

Deep-water, heterotroph-mixed skeletal-microbial reef communities are known from the Silurian to Devonian, Jurassic, and Cretaceous. They were very different from

modern skeletal deep-water reefs. Muddy reefs with *Stromatactis* (Figure 8), lithistid sponges, and calcimicrobes were widespread during the Silurian, and typically show a vertical zonation that culminates in shallow-water stromatoporoid sponge-rich communities. Similar communities, with the addition of microbialites, stromatolites, and receptaculitids, formed deep-water reefs in the mid-to-late Devonian.

**General Evolution of Carbonate Reefs, Figure 6** (a) Late Devonian (Frasnian) reef, showing a large branching stromatoporoid sponge, encrusted by microbialite and *Renalcis*. Cavities are filled with syndeposimentary sediment and cement. Windjana Gorge, Canning Basin, Western Australia; scale = 5 cm. (b) Pendent sponges growing downward attached to a bryozoan frond. The whole framework has been encrusted with microbialite. Remaining cavity space is filled with syndeposimentary cement botryoids. Permian Capitan Reef, McKittick Canyon, Guadalupe Mountains, Texas, USA. Field of view = 6 cm.

Upper Jurassic deep-water mixed reefs were constructed by thrombolitic–stromatolitic columns or mounds associated with *Tubiphytes*, the worm *Terebella*, and hexactinellid and lithistid sponges. The platy scleractinian coral *Microsolena*, which is thought to have fed in part heterotrophically, is found in low-light settings, such as shallow turbid or deep-water environments.

### Microbial reefs

Modern stromatolites are relatively rare and appear to grow in areas of abundant calcium carbonate saturation and where faster-growing algae and seaweeds are excluded due to some environmental stress such as active tidal currents, low nutrients, or high salinity (Figure 9b).

Microbial reefs dominated much of earth history, from the Archean until Middle Ordovician, but they are only found in younger Phanerozoic facies, where most invertebrates have been excluded by environmental stresses. They are built primarily by stromatolites and thrombolites that have a wide variety of morphologies. Precambrian reefs throughout the Archean, early, and middle Proterozoic are essentially a series of stacked stromatolites and, to a lesser extent, thrombolites (Grotzinger and James, 2000). They have neither cavities nor inter-microbial syndeposimentary cements but exhibit a wide variety of delicate branching, lamellar, hemispherical, and conical morphologies that are thought to be due to a combination of different microbial communities, hydrodynamics, and sedimentation rates. These microbialites range in size from centimeter to decimeter, with some large structures up to 8 m high and 30 m long.

Shallow-water, high-energy Proterozoic buildups were formed by isolated stromatolitic domes, linked domes, columnar stromatolites, and their elongate equivalents. Stromatolite fragments were ripped off during storms and deposited as cross-bedded gravels locally surrounded

by individual shallow reefs. Reefs at platform margins show a strong zonation of microbialite growth forms that mimic facies zonations of metazoan reefs. Isolated deep subtidal and slope reefs (probably below fairweather wave base) were built primarily by conical stromatolites.

There seems to be an evolution of microbial structures through the Precambrian. Archean and Palaeoproterozoic reefs were mainly syndeposimentary precipitates (possibly microbially mediated) with microbial layers. Microbes appear to become more prominent in Paleoproterozoic and Mesoproterozoic structures. A profound change, however, took place in the Neoproterozoic with the increased importance of thrombolites and the appearance of calcimicrobes as reef builders (Figure 9a). This resulted in the earliest formation of cavities complete with internal sediment and syndeposimentary cement, features that would become a prominent attribute of all subsequent Phanerozoic reefs. This community had the ability to construct reefs with up to 100 m of relief above the sea floor in deeper water environments (Turner et al., 1997). Toward the end of the Neoproterozoic, the first skeletal invertebrates (e.g., *Cloudina*, *Namacalathus*, and *Namapoikia*) began to populate the surfaces of these reefs and were entombed by the microbial precipitates.

### Mud mounds

Mud mounds can form large, often over 100-m high and 400-m wide, isolated, steep-sided structures that consist of more than 80% of a fine-grained carbonate (micrite) (Figure 8b). This micrite has both in situ and detrital origin but often shows accretionary structures constructed by successive phases, known as polygenetic muds (“polymuds”), which form on open surfaces and within semi-enclosed cavities (Monty et al., 1995). Such polymud fabrics produce complex, three-dimensional accumulations that in turn form open frameworks that

**General Evolution of Carbonate Reefs, Figure 7** (a) Growth cavity in archaeocyath skeletal-microbial reef mound. The cavity is formed by the calcimicrobe *Renalcis* and populated by pendent, solitary archaeocyaths. Lower Cambrian, Siberia, Russia; scale = 5 mm. (b) Reconstruction of lower cambrian archaeocyath community. 1. *Renalcis*, 2. branching archaeocyath sponges, 3. solitary cup-shaped archaeocyath sponges, 4. chancelloriid, 5. radiocyaths, 6. small archaeocyath sponges, 7. "coralomorphs," 8. large archaeocyath, 9. fibrous cement, 10. microburrows, 11. cryptic archaeocyaths, 12. cribricyaths, 13. trilobite trackway, 14. cement, 15. internal sediment. (From Wood, 1999; Copyright J. Sibbick.)

may subsequently be filled with mud or syndimentary cement. Many mounds also display a rich attached metazoan biota of crinoids, tabulate corals, brachiopods, trilobites, sponges, ostracodes, and bryozoans.

The clotted, peloidal or laminated textures, and the encrusting or frame-forming habit argue for an *in situ* microbial or organomineralic origin, augmented by a rapid

syndimentary lithification. This origin is supported by moderate rates of carbonate accumulation (0.2–0.8 m/1,000 years), and the steepness (35–40°) of mound flanks. Abundant *Stromatolites* cavities that parallel the accretionary mound surfaces (Figure 8a) suggest a close relationship between mound formation and internal sediment filled voids, cementation, and carbonate production (Monty et al., 1995).

**General Evolution of Carbonate Reefs, Figure 8** (a) Irregular masses of calcite (*Stromatactis*) that were originally internal cavities partly filled with internal sediment and then occluded by syndimentary cement in a late Devonian (Famennian), Windjana Gorge, Canning Basin, Western Australia; scale = 5 cm. (b) Muleshoe Mud Mound, Mississippian, Sacramento Mountains, New Mexico, USA.

**General Evolution of Carbonate Reefs, Figure 9** (a) Neoproterozoic thrombolites, Nama Basin, Namibia. (b) Living stromatolites in Shark Bay, Western Australia.

Mud mounds were often established in deep waters below the photic zone as indicated by the absence of algae and cyanobacterial activity. Locally, however, they show shallowing-upward facies signatures, characteristic of shallow depths and significant depositional energies. In the Frasnian “*récifs rouges*” of the Belgian Ardennes, the basal facies is composed of *Stromatactis*-rich red lime mudstone to wackestone with abundant sponge spicules. This may have formed in hypoxic waters below the photic zone. Platy corals appear higher but are overlain by a more diversified coral, stromatoporoid, and skeletal algae wackestone to packstone with *Stromatactis*. Uppermost facies consist of a stromatoporoid, coral, and bryozoan framework with various microbial and calcimicrobial encrusters, which formed in photic waters above fair-weather base and sometimes in restricted or lagoonal environments.

Early Mississippian reefs (Waulsortian facies) also show a similar progression of facies. The growth of the

well-known Muleshoe Mound in New Mexico (Figure 8b) records a shift from predominantly upward (aggradational) to lateral (progradational) growth. The largest volume of these buildups is composed of polymud fabrics with early cements, sponges, and large fenestrate bryozoans. The framework is composed of rigid micrite masses with rounded, bulbous shapes, and thrombotic fabrics that are lined by early marine cements. In the uppermost facies, both the microbialites and large bryozoans grew with a pronounced high-angle orientation into currents. Crinoid-rich flanking grainstone beds draped the reef slopes. In places, fenestrate bryozoans built a delicate framework that formed a limestone containing up to 90% of early fibrous cement.

The location and initiation of mud-mound formation appears to be mediated by environmental factors that differ from those of shallow skeletal reefs. Indeed, there may therefore be real differences in the style of primary production and organic matter recycling between these

different reef systems. Deep-water mud mounds are commonly found in groups, suggesting that their formation was environmentally mediated. Several environmental triggers have been proposed: the episodic formation of nutrified water masses reduced sediment supply during platform drowning or localized oxygen depletion of seawater. Some mud mounds are aligned along faults or fissures, which may have acted as conduits for hydrothermal fluids. For example, the microspars and brachiopods of Muleshoe mound have been shown to have higher  $\delta^{13}\text{C}$  values than non-mound samples, possibly related to methanogenic fermentation.

Mud-mound formation began in the Palaeoproterozoic (probably Neoproterozoic) and extended until the Miocene, but they are mostly a Palaeozoic phenomenon, with widespread mud-mound formation occurring during the early Cambrian, the lower Ordovician, the late Devonian, and the Mississippian, which was dominated by Waulsortian mounds.

### Origin of the modern coral reef ecosystem

The modern coral reef ecosystem is geologically very young. Scleractinian corals appeared in the mid-Triassic and had almost certainly acquired photosymbionts by the late Triassic at the latest (Stanley and Swart, 1995). The ancestral stock of the modern reef biota appeared in the middle Jurassic but was largely suppressed by the prolific growth of calcitic rudist bivalves in the Cretaceous, only to rebound after the end-Cretaceous extinction. There is considerable debate, however, as to whether this coral-dominated biota was able to construct spectacular large reefs like those of the modern day before the Cenozoic.

Most modern coral genera appeared in the Eocene–Miocene, and many extant species extend back no further than the Pliocene. Modern reef fish appeared in the Eocene, but the oldest record of parrotfish (scarid) remains are from Miocene sediments dated at 14 million years ago (Ma).

During the Oligocene, the compression of climatic belts and the rise of the Isthmus of Panama created two distinct regions of reef growth to the Caribbean and Indo-Pacific. As a probable result of climatic cooling or habitat loss, a major episode of coral faunal turnover ensued between 4 and 1 Ma in the Caribbean (Budd et al., 1994). Extinction of genera in the Pocilloporidae and Agaricidae was most marked, but many of these genera continued to persist in the Indo-Pacific. A similar differential extinction coincident with corals, removed many fish, including all large excavating scarids, herbivorous siganids, and plantivorous caesionids from Atlantic reefs (Bellwood, 1997).

Although acroporid corals appeared in the Eocene, pocilloporids appear to have dominated Caribbean reefs from 5 to 6 Ma, but following a 1-million year (Myr) transition period of mixed acroporid–pocilloporid assemblages, acroporids became dominant in reef communities in the early Pleistocene (approx. 1.6 Ma). Acroporids may not, however, have achieved levels of extreme abundance until the late Pleistocene (approx. 0.5 Ma)

(Budd and Kievan, 1994). With this as yet unexplained rise to dominance of branching *Acropora*, and a corresponding decline in massive, domal corals, coral reef communities with a completely modern aspect appeared about 0.5 Ma. Except for the extinction of *Pocillopora* in the Caribbean at about 60,000 years (ka), the patterns of community membership and dominance of coral species appear to have been highly predictable for at least the past 125,000 years (Kyr) (Pandolfi and Jackson, 2001).

### Response to long-term environmental change

Climate and changing seawater chemistry are important controls on the history of reef growth, in terms of both complex feedback mechanisms that govern skeletal mineralogy and hence promote some groups over others, and controlling the styles of early lithification.

Tectonics ultimately drives many aspects of reef growth such as sea level, circulation patterns, climate, and evolving seawater chemistry change over long timescales (Figure 10). Reefs and carbonate platforms commonly initiate on preexisting highs such as horst blocks or salt domes during the early stages of rifting. Reefs are most numerous on passive continental margins at low latitudes where they typically form barrier or fringing reefs. Similar carbonate shelves with reefs can form around the margins of shallow intracratonic basins, where they can be interbedded with evaporites. Such basins may be prone to isolation from the open ocean, leading to infilling by extensive evaporites.

Rates of thermal subsistence on passive margins are slow and predictable and are similar to those found in intracratonic basins. Reef geometries are thus generally compound to progradational. By contrast, reef-forming toward the cratonward side of foreland basins is relatively rapid and reef geometries more aggradational. Finally, reefs forming in strike-slip basins and on thrust complexes are affected by the vagaries of local tectonic movements, which may be highly episodic but involve substantial displacements and are thus highly unpredictable.

Epeiric seas, those that formed by the extensive flooding of continents during globally high sea levels, have negligible basin floor topography. Water depths rarely exceeded 10 m, such that shallow subtidal and intertidal sediments dominate, with many episodes of exposure. Epeiric seas could support patch reefs, often elongated because of wind waves, storms, or tides. Due to the limited accommodation space on epeiric platforms, progradation is the dominant depositional process, resulting in stacked shallowing-upward sequences or biostromes.

### Climate

Climate is a major controlling force on the evolution of reefs on both short and long timescales, as the latitudinal range of carbonate-producing species is largely governed by temperature and carbonate supersaturation. Reef growth therefore shows cyclicity at all scales in response to short-term

**General Evolution of Carbonate Reefs, Figure 10** (a) Correspondence between changing ocean chemistry and carbonate mineralogy through time as a function of the Mg/Ca mole ratio in seawater (Stanley and Hardie, 1998) and general global sea-level change (Vail et al., 1977); the boundary between the fields of calcite ( $<4$  mole%  $\text{MgCO}_3$ ), and high-Mg Calcite ( $>4$  mole%  $\text{MgCO}_3$ ) and aragonite is the horizontal line at  $\text{Mg/Ca} = 2$ ; (b) the different dominant nonskeletal mineralogies precipitated in seawater through time (Sandberg, 1983); (c) the different global climatic and oceanographic periods (Fischer, 1982); (d) mineralogy of different reef-building organisms (Stanley and Hardie, 1998). (From James and Wood, 2010.)

oscillations (e.g., Milankovitch and glacial–interglacial cycles) as well as to longer-term climatic intervals driven by slower, tectonically driven processes.

Global climate has oscillated through greenhouse and icehouse phases, in concert with aragonite and calcite seas, respectively (Figure 10). During icehouse times of continental glaciation (e.g., Pennsylvanian–early Permian, Miocene–Pleistocene), high-frequency sequences on carbonate platforms were generated by eustatic sea-level changes of 50–100 m. Subaerial exposure, unfilled accommodation space, and conspicuous regional disconformities were common. Aggrading reef growth in a keep-up mode is dominant in icehouse times, as rates of production barely match those of accommodation space increase. These large changes in sea level caused ramps

to have steep gradients and platform tops to have significant depositional relief, characterized by pinnacle reefs and erosional topography. Icehouse reefs are typically dominated by heterotrophs or autotrophs with aragonitic or high-Mg mineralogies.

During greenhouse times with little global ice (e.g., late Cambrian–early Ordovician, Devonian, Triassic, Cretaceous), reef sequences were generated by small (possibly  $<10$  m or so) sea-level fluctuations. Reef cycles typically consist of very shallow-water facies, with regional-scale tidal flat caps and minor disconformities. Greenhouse reefs are often either compound or progradational as reef growth could easily match or outpace the fastest rates of sea-level rise. TST reefs, with plenty of accommodation space were continuously in catch-up or keep-up mode, and this part

of the reef is normally the thickest but narrowest. Ramps often have very low gradients and platforms tend to be progradational, with minor topography. Greenhouse reefs can also have a more extensive range as carbonate settings extend into higher latitudes due to elevated global temperatures. Composition may also be more uniform, often dominated by low-Mg calcite skeletal components.

### Carbonate saturation

Living coral reefs are restricted to shallow-water tropical and subtropical environments characterized by warm temperatures, high light intensities, and also high aragonite supersaturation. The growth of coral skeletons and other calcifying organisms precipitates carbonate ions, forcing a re-equilibration of the bicarbonate-dominated marine inorganic carbon system which also creates a source of carbon dioxide. A coral reef therefore represents the net accumulation of  $\text{CaCO}_3$  and a source of  $\text{CO}_2$ , which in turn probably leads to feedback-controls on the global carbon cycle.

Carbonate saturation has probably varied dramatically throughout geological time. It appears that Precambrian oceans were highly oversaturated, but this may have declined around the beginning of the Phanerozoic with the appearance of numerous calcareous invertebrates. Since then,  $\text{Ca}^{2+}$  in seawater has broadly followed sea-level change such that  $\text{Ca}^{2+}$  levels were reasonably high during the Cambrian-Mississippian and the Jurassic to Cretaceous.

It has been suggested that the geological distribution of microbialites might be controlled by physicochemical factors, including the saturation state of seawater and/or global temperature distribution (Webb, 1996). This may also explain the decline in abundance of reef microbialite after the Jurassic due to the increase of pelagic carbonate that led to a reduced seawater saturation state. This would have lowered supersaturation levels below a threshold for abundant automicrite formation, thus restricting its formation to cryptic reef habitats, where abnormal chemistries could have existed. Such a situation might also explain the absence of *Stromatolites* in the late Phanerozoic.

### Evolving ocean chemistry

The dominant form of precipitated crystalline  $\text{CaCO}_3$  has oscillated during the geological past, with both inorganic and organic production of aragonite and high-Mg calcite dominating carbonate formation during cool periods (ice-house), and low-Mg calcite predominating during warm periods (greenhouse) (Figure 10). Such mineralogical shifts are interpreted as markers for major changes in seawater chemistry.

Stanley and Hardie (1998) have proposed that the shifts in the Mg:Ca ratio have controlled the predominance of calcite versus aragonite secretors, particularly reef builders, due to the inhibiting effect of high  $\text{Mg}^{2+}$  concentration on calcite secretion. They suggest that the changing Mg:Ca ratio of seawater has been controlled by variations in the rate of production of oceanic crust, because oceanic hydrothermal alteration is a major sink for Mg and an

important source of Ca. Experimental work has subsequently confirmed the profound influence of Mg:Ca seawater ratios on modern reef builders, including scleractinian corals (Ries et al., 2006) and the calcareous green alga *Halimeda*.

Scleractinian corals were, for example, important reef builders in the Jurassic, but they did not build extensive reefs during the greenhouse period (calcite seas) of the Cretaceous. During this period, species diversity remained high but their abundance on carbonate platforms was low compared to the Jurassic. Distribution shifted to outer platform settings and higher latitudes ( $\sim 35\text{--}45^\circ \text{N}$ ). There are many hypotheses offered to explain these observations, including the high temperatures, restricted circulation, and unstable sediment conditions of Cretaceous platforms, and in particular the favoring of calcite-producing rudist bivalves over aragonite corals (Wood, 1999). Rudist bivalves with their outer calcitic skeletons underwent a dramatic radiation in the late Cretaceous when the Mg:Ca ratio of seawater reached exceptionally low values so favouring calcite over aragonite secretors (Steuber, 2002).

Major shifts in the dominant composition of carbonate skeletal particles through geological time also mirrors in part these proposed changes in seawater chemistry and climate (Figure 10d), but mass extinctions also play a role by triggering changes in the predominant form of  $\text{CaCO}_3$  produced by marine calcifiers (Kiessling et al., 2008). Changes in the abundance of aragonitic organisms following mass extinction events appear to have been predominantly driven by selective recovery rather than selective extinction.

Evidence is also persuasive that the changing seawater chemistry has influenced the style of early diagenesis in carbonate regimes, particularly in reefs. The mineralogy of early marine reef cements also seems to follow the same secular changes. For example, aragonitic botryoids are known exclusively from phases of aragonite seas (early Cambrian, mid-Carboniferous to early Jurassic, and mid-late Cenozoic), whereas radial fibrous calcite is common in reefs that grew in calcite seas (particularly the Ordovician to Devonian); it is virtually unknown from aragonite seas of the Cenozoic. Enhanced rates of calcite cementation during calcite seas due to the elevated abundance of calcium ions may have promoted rapid lithification of the reef framework and aided preservation of cryptic biota that were otherwise vulnerable to disturbance, but this has yet to be documented.

### The rise of predation and bioerosion

Many researchers have summarized the importance of herbivores and large marine vertebrates to the healthy functioning of coral reefs, and this importance is corroborated by analysis of the fossil record (see Wood, 1999, 2002). A dramatic escalation of new organisms with innovative and destructive feeding methods occurred from the mid-Jurassic to Miocene (summarized in Vermeij, 1987). In particular, the arrival of piscine herbivores had

the potential to fundamentally alter the dynamics of reef and other benthic marine communities.

In general, grazers and carnivores throughout the Palaeozoic and early Mesozoic were relatively small individuals with limited foraging ranges incapable of excavating calcareous substrates. A radiation during the Devonian of durophagous, mobile predators has been proposed by Signor and Brett (1984), but these forms probably relied upon manipulation only to crush or ingest (Harper and Skelton, 1993). By the early Mesozoic, sessile organisms had to contend with an increasing battery of novel and more advanced feeding methods as well as sediment disruption due to deep bioturbating activity (see summary in Vermeij, 1987). Most notable was the rise of efficient excavation behaviors.

Bioerosion notably increased in intensity from the mid-to-late Jurassic. A radiation of borers occurred from the Triassic onward, with deep borers (capable of penetration greater than 50 mm) appearing from the Jurassic. Clionid sponges – one of the major bioeroders on modern coral reefs – had become abundant by the latest Jurassic. The first live borers are known from the Eocene (Krumm and Jones, 1993), as are fishes similar to modern reef faunas (Bellwood, 1996). The ability for substantial excavation of hard substrata over large areas increased considerably from the latest Cretaceous-early Tertiary when deep-grazing limpets, camarodont sea urchins, and especially the reef fishes appeared. The complex pharyngeal apparatus of labrids was present at this time, and major labrid clades were already differentiated (Bellwood, 1997). Balistids first appeared in the Oligocene, and the oldest scarid fossil capable of deep excavation currently known

is from the Miocene (14 Ma) (Bellwood and Schulz, 1991). It seems likely that sometime during the Oligocene–Miocene, reef bioerosion gained a modern caste.

The abundance of reef fishes is assumed to be of great importance on coral reefs, as evidenced by the dramatic increase of algal growth as a result of their decline on Jamaican reefs. Tropical marine hard substrata are usually sparsely vegetated, but a rich algal flora develops when herbivorous fish are excluded and/or nutrient input increases. Grazers not only allow the dominance of corals and coralline algae on coral reefs, they also contribute notably to carbonate sediment production and redistribution, algal ridge formation, and the maintenance of overall diversity. Like other predators, they can also ameliorate the effects of competition and may combine with physical controls to produce the characteristic zonation of modern coral reefs.

The response of reefs to predation has been reviewed by Wood (2002, in press). Table 1 outlines the major causes and indirect effects of predation, particularly herbivory, on coral reef communities. From this, we might be able to make a series of predictions concerning changes in post-Palaeozoic reef community ecology based on their rise to abundance in the fossil record. In the sections following, these predictions are tested in order to determine to what extent the evolutionary history of reef-bioerosion and bioturbation has been bound with the ecology and taphonomy of reef ecosystems.

### Response to increased biological disturbance

Only skeletal anatomy and morphology, spatial distribution, and skeletal attack or breakage, and regeneration might be detected – or inferred – in the fossil record of

**General Evolution of Carbonate Reefs, Table 1** Predicted changes in reef community ecology and taphonomy based on the rise to abundance of new predatory methods and endoliths as evidenced in the fossil record. (After Wood, 1999, 2002)

|                                              | Formation of sediment aprons                                                                                                  | Miocene                             |
|                                              | Thick coralline algal crusts                                                                                                  | Miocene                             |
|                                              | Reduction in rate of reef progradation                                                                                        | Miocene                             |

reef organisms. The appearance of these herbivores paralleled profound changes in reef ecology, including the rise of well-defended, highly tolerant coralline algae (Steneck, 1985), a notable increase in branching corals since the late Cretaceous (Jackson and McKinney, 1991), and the loss of many functional organisms that prove to be intolerant to excavatory attack (Table 1). This suggests a cause–effect system, where adaptation to predatory attack has been intimately bound to the origin and assembly of modern reefs.

#### *Secure attachment to a hard substrate*

Organisms without secure attachment to a stable substrate are susceptible to the effects of all disturbances, including bioturbation, as inversion and burial will cause death. Most modern suspension feeders require a hard substrate, even if these are only isolated patches within areas of unstable, soft substrate.

Possession of an edge zone in all but the most primitive scleractinian corals allows them to gain permanent attachment to a stable substrate. As a result, scleractinian corals dominate modern reef framework environments, especially those in high-energy settings, where there is also an abundance of wave-swept, extensive hard substrata for colonization. Permanent attachment also allows the development of very large branching morphologies.

Cambrian archaeocyath sponges usually bore small holdfasts that enabled limited attachment to hard substrates (Figure 7a). But many mid-to-late Palaeozoic reefs were dominated by large, sheet-like invertebrates (stromatoporoid sponges, tabulate and rugose corals, and trepostome and cystoporoid bryozoans) that were initially attached to small, ephemeral skeletal debris and then grew over the surrounding sediment (Figure 5). Small, branching forms (some stromatoporoids and bryozoans) lacking extensive attachment sites were also common, and they were presumably partially rooted in soft sediment.

The late Paleozoic decline of immobile epifauna coincides with the rise of major bulldozing taxa, which passed through the end-Permian extinction unscathed. This coincidence must remain conjectural until tested experimentally.

#### *Resistance to partial mortality*

Predation that actively excavates underlying skeleton often results only in partial mortality, that is, sublethal damage. In such cases, the capacity of the prey to heal or replace damaged areas of soft tissue becomes critical to survival. Strategies that rely upon herbivores/predators to remove competing algae therefore often entail the loss of the prey's own tissues.

In coralline algae, a protective outer epithallus and conceptacles that contain reproductive structures have been demonstrated to protect the delicate reproductive anatomy from intensive grazing (Steneck, 1982). Many coralline algae can also tolerate intense herbivory due to their ability to rapidly regenerate removed material. Thickened

crusts are more tolerant to attack than thin encrusting or branching forms (Steneck, 1985), but in modern reefs, the dominance of a particular growth form appears to be a trade-off between the cost of investment in increased defence, and the reduction in growth rate or competitive ability. As a result, thickened crusts dominate only in areas of high wave energy and biological disturbance.

After the Eocene, herbivore-susceptible, delicately branched coralline algae reduced in abundance in the tropics, the proportion of thickened encrusting forms increased, and the first algal ridges appeared – all coincident with the rise of excavatory herbivorous fish.

Many sessile reef organisms possess a modular or colonial habit where partial predation and boring may remove either individual or a few modules, or large areas may be cleared of living tissue, sometimes together with the excavation of underlying skeleton. But the modular organization also reduces soft tissue to a relatively thin veneer over a larger basal skeleton. This not only decreases accessibility and the ease of prey manipulation by predators but also minimizes the tissue biomass while maximizing the cost of collection. For example, in a typical domal colony of *Porites*, only about 0.5% of the colony's radius is occupied by soft tissue (Rosen, 1986). In branching and platy colony forms, the relative proportion of skeleton is even higher.

Cambrian archaeocyath sponges show a steady and marked increase in the proportion of complex modular forms during their history (Wood et al., 1992), as do scleractinian corals since the mid-Triassic, which appears to be uninterrupted by the end-Cretaceous extinction event (Coates and Jackson, 1985).

#### *Regeneration after breakage*

Some morphologies are more resistant to breakage than others. For example, colonies with closely spaced branches can make predator access difficult by forming hidden, protected areas. The flattening of branch terminations can also offer greater resistance to all forms of breakage and shearing, and this character is found in erect species of bryozoans, gorgonian corals and stylasterine corals.

A multiserial modular organization, however, in addition to promoting architectural diversity and flexibility, also allows compartmentalization of damage and enables some colonies to regenerate from fragments. Most significantly, branching corals also show tremendous powers of regeneration: *Acropora palmata* has one of the highest rates recorded. Indeed, unlike massive, platy or encrusting forms, damage to branching corals often leads to an immediate increase in growth rate so causing an increase in size rather than simply repairing damaged tissue. The staghorn coral (*Acropora cervicornis*) is able to re-anchor fragments and rapidly regenerate and grow, often fusing with other colonies. Such branching corals have turned adversity into considerable advantage, and appear to flourish because, and not in spite, of breakage.

The percentage of scleractinian erect species decreased until the late Cretaceous (Turonian), but increased markedly – particularly in multiserial forms with inferred rates of rapid regeneration – after that time. This spectacular rise of various morphologies of branching forms was coincident with the appearance of new groups of predatory excavators.

All families of modern scleractinian corals that dominate reefs today spread throughout the Tethys Sea during the Eocene. The poritids, their relatives the actinids, and the favids (which had survived the Cretaceous extinction) dominate most coral reef communities throughout much of the Cenozoic (McCall et al., 1994). Although branching acroporoids appeared in the Eocene, they did not dominate reefs until early Pleistocene. The rise of this group – with its particularly remarkable powers of regeneration from fragmentation and rapid growth – would then seem to be independent of any known changes in predation style.

#### *Patterns of sediment removal and storage*

Unlike modern reefs, anecdotal evidence suggests that a greater proportion of reef framework is preserved in situ before the Jurassic (Wood, 1999). Many Palaeozoic reefs commonly preserve intact reef frameworks, even of fragile biota such as frondose bryozoans (Figure 6b) or platy stromatoporoid sponges. Such preservation was aided, in part, by abundant and probably rapid syndimentary lithification, particularly cementation.

We might predict that substantial aprons of sediment may not have been present on pre-Eocene reefs before the evolution of reef fish, and likewise in the absence of the grain size reduction activities of clionid sponges, echinoids, fish, mean sediment grain size may have been more coarse prior to the late Jurassic, perhaps resulting in a reduced net loss of carbonate to the system through the removal of fines. It is possible also that the modern style of coral reef lagoon may also not have appeared until the late Jurassic or later (Wood, 1999, 2010).

### **The role of mass extinctions**

Reefs have long been thought to be highly susceptible to mass extinction events, with major reef-building biota typically going largely or wholly extinct. Metazoan reefs may take some 2–8 Myr to recover after such events, sometimes longer than other communities, and post-extinction reefs are often composed of entirely new groups of skeletal metazoans.

In some cases, either calcimicrobes or microbialites can dominate post-extinction reefs, but these elements were often already part of the pre-extinction reef community. Shallow-water Frasnian (late Devonian) reefs show abundant large skeletal metazoans (particularly stromatoporoid sponges, and subsidiary corals) as well as extensive fenestral microbialite and calcimicrobes both as free-standing mounds (Figure 5b). Succeeding Famennian reefs growing in the aftermath of a mass extinction were composed of frame-building microbialite and calcimicrobes (e.g., *Renalcis* and *Rothpletzella*) and a diverse community of

spiculate sponges. The first metazoan reefs to form after the end-Permian extinction in the Anisian (Lower Triassic) bore large framework cavities, populated with the calcified microbe *Cladogirvanella*.

Tropical shallow marine carbonate production has been noted to fall after some mass extinctions (e.g., the late Devonian and end Permian), but not others (end Cretaceous). Changes in seawater saturation or chemistry may also explain the response of reef and other carbonate-producing biota to mass extinctions. When skeletal groups first appear, they tended to adopt the mineralogy favored by ambient seawater chemistry, but subsequent extinction events may have preferentially removed those groups and selected for new skeletal biota whose skeletal mineralogy reflected the new ocean chemistry (Kiessling et al., 2008).

### **Summary**

Reefs have shown some unifying features over their 3.5-billion-year history. Reefs have shown zonation in response to environmental gradients from their inception, and metazoan reefs have been differentiated into open surface and cryptic reef communities for their entire ~550-million-year history (Wood et al., 2002).

Tectonics drives many aspects that control reef growth including sea level, circulation patterns, climate, and evolving seawater chemistry change over long timescales. Reefs have always been most numerous on passive continental margins at low latitudes where they typically form prograding or aggrading barriers (with growth during transgressive and highstand periods and erosion during longer low stand periods), or fringing reefs. By contrast, reef-forming toward the cratonward side of foreland basins is relatively rapid and reef geometries more aggradational. Finally, reefs forming in strike-slip basins and on thrust complexes are affected by the vagaries of local tectonic movements, which may be highly episodic but involve substantial displacements and are thus highly unpredictable (James and Wood, 2010).

Climate is a major controlling force on the evolution of reefs on both short and long timescales, as the latitudinal range of carbonate-producing species is largely governed by temperature and carbonate supersaturation. Reef growth therefore shows cyclicity at all scales in response to short-term oscillations (e.g., Milankovitch and glacial–interglacial cycles) as well as to longer-term climatic intervals, driven by slower, tectonically driven processes.

Global climate has oscillated through greenhouse and icehouse phases, in concert with aragonite and calcite seas, respectively. During icehouse times of continental glaciation, high eustatic sea-level changes created aggrading reef growth, common subaerial exposure and conspicuous regional disconformities in reef complexes. These large changes in sea level caused ramps to have steep gradients, and platform tops to have significant depositional relief characterized by pinnacle reefs and erosional topography. Icehouse reefs are typically dominated by heterotrophs or autotrophs with aragonitic or high-Mg mineralogies.

During greenhouse times, with little global ice, reef sequences were generated by small sea-level fluctuations. Reef cycles typically consist of very shallow-water facies, with regional-scale tidal flat caps and minor unconformities. Greenhouse reefs are often either compound or progradational as reef growth could easily match or outpace the fastest rates of sea-level rise. Ramps often have very low gradients, and platforms tend to be progradational, with minor topography. Greenhouse reefs can also have a more extensive range as carbonate settings extend into higher latitudes due to elevated global temperatures. Composition may also be more uniform, often dominated by low-Mg calcite skeletal components.

Biological disturbance, that is bioturbation, boring, and excavatory predation and herbivory, has clearly escalated since the Mesozoic. Reef biotas have responded with the proliferation of traits with proven anti-predatory benefits, particularly regeneration after partial mortality. Indeed some modern dominant reef taxa, such as branching corals and coralline algae, appear not only to thrive, but actually require conditions of considerable disturbance for their survival in shallow tropical seas (Wood, 1999, 2002).

Many modern reefs are largely reduced to rubble and sand via physical abrasion and bioerosion. Modern coral reefs are also dominated by branching forms due to their high diversity and abundance, propensity to proliferate via fragmentation, and resilience to taphonomic destruction. Many reefs prior to the Jurassic show the preservation of intact, in situ frameworks. Most epibenthic, soft-sediment dwelling organisms typical of Paleozoic reefs appear to have become largely absent from shallow marine tropical reef biotas during the late Paleozoic to early Mesozoic, perhaps due to intolerance of the rise of deep burrowing taxa and excavatory attack (Wood, 2010).

Scleractinian corals, in particular branching taxa, show a marked increase in the proportion of forms with complex modularity from the Eocene onward, even though corals displayed the full range of morphological forms and corallite size by the Late Triassic. Highly defended, thick crusts in coralline algae become more dominant, and branching forms also become noticeably less conspicuous on reefs from the Eocene onward. This major reorganization of the coral reef ecosystem coincides with the rapid appearance and radiation of herbivorous and coral-eating reef fish, but this remain to be tested experimentally (Wood, 2002).

## GEOMORPHIC ZONATION

Paul Blanchon  
 National Autonomous University of Mexico, Cancun,

## Introduction

The coral reefs of the Atlantic, the Caribbean and the Indo-Pacific do not differ fundamentally in their structural forms, their habitats and the interaction of their species, even though the organisms occupying specific ecological roles vary greatly between oceans and even between individual reefs. Goreau et al. (1979, p. 135)

Despite the similarity between the geomorphology of coral reefs noted by the Goreaus and others (Wells, 1957; Stoddart, 1969), much of the emphasis in characterizing coral-reef zonation has been ecological using either statistically defined coral assemblages or more simply,

the morphology of the corals themselves (Wells, 1957; Rosen, 1975; Geister, 1977; Pichon, 1978; Chappell, 1980; Done, 1982; Done, 1983). Most of these studies have found that shallow coral assemblages show a distinct zonation as wave energy, and hydrodynamic disturbance varies with depth and margin exposure. For example, Done (1982) found that shallow communities changed with a decreasing cross-shelf wave exposure in the central Great Barrier Reef. Individual reefs also showed the same pattern, with shallow-wave-adapted communities being replaced along leeward margins by upward shifts in the positions of deeper communities. Growth form of corals also show similar zonation patterns in response to depth and exposure-related variation in wave energy (Pichon, 1978; Chappell, 1980; Madin and Connely, 2006). Such zonation patterns have led to a clear distinction between rough-water reefs exposed to trade-wind-, swell-, and storm-generated wave fields and calm-water reefs protected from them (Geister, 1977, 1980).

A comparison of zonation schemes, however, shows that the coral assemblages in each zone can be highly variable on both inter-reefal and regional scale, and there is a significant overlap between the members of each assemblage zone (e.g., Done, 1982). Despite this “coral-scale” variability, the geomorphology of these reefs is very similar. Indeed, equally similar reef structures are produced in areas with order-of-magnitude differences in species abundances, and even where reefs have depauperate species numbers, their basic geomorphology is identical (e.g., Glynn et al., 1996). This consistency implies that gradients in wave exposure not only control the main environmental tolerances of shallow coral assemblages but also the form of the structures they build (Graus et al., 1977; Graus et al., 1984, 1985; Graus and Macintyre, 1989). It therefore follows that reefs might be better classified according to their geomorphic form (Wells, 1957).

Until very recently, a synoptic view of reef geomorphology showing the impact of varying ecological processes has not been possible, and previous attempts to summarize information have had to rely on parochial descriptions of what was accessible or visible at the time (e.g., Hopley, 1982; Guilcher, 1988). Following this approach, vast areas of modern reefs have been inadequately characterized and, with some exceptions, quantitative differences and the similarities between different regions have gone undocumented. This deficient situation is about to change. The recent advent of widely available orthorectified satellite imagery (Google Earth) and rapid development and cost reduction in geographic information systems, multi-beam sonar, LiDAR, and other remote-sensing technologies are making large-scale morphometric quantification of reefs feasible (Naseer and Hatcher, 2001; Andrefouet et al., 2001; Storlazzi et al., 2003; Naseer and Hatcher, 2004). As such, we are on the cusp of being able to provide a more holistic view of modern coral-reef form and a development that will provide

timely insight into the resilience and resistance of reefs to human-induced global environmental change.

In this entry, I examine satellite imagery using Google Earth along with local descriptions of reefs and attempt to summarize what is presently known about the geomorphic zonation of well-ordered, rough-water reefs, outline their formative processes, and assess their development.

### Standard geomorphic reef zonation

A comparison of well-ordered, rough-water reefs shows a remarkable degree of conformity between the size and character of their major morphological features (Figure 1). All of them consist of five first-order or “standard” zones: a calm reef lagoon, with varying number of patch reefs; a largely barren, shallow reef flat strewn with detritus; a narrow, gently sloping reef front exposed to waves and swells; a steeper reef slope bearing corals to as deep as 100 m; and a less steeply inclined fore-reef apron, where coral and reef detritus accumulate. The boundaries between these standard zones are delineated by simple slope breaks. The break between the lagoon and the reef flat is either a sand slope or a small reef scarp. The break between the level reef flat and the gently sloping reef front occurs at the reef crest. Similarly, the shelf break separates the gently sloping reef front from the steeper reef slope, and the break between the reef slope and fore reef is the transition into slopes that reflects the angle of sediment repose. Each of these standard and easily defined reef zones can in turn be subdivided into commonly recurring second-order zones or subzones, which may not be present on all reefs and, if they are present, may vary between margin, area, and region. As a consequence, their boundaries can be more difficult to define.

### Lagoon

With their calm, stable environments, and depth ranges that are usually within the range of coral growth, lagoons potentially represent an ideal and extensive habitat for reefs (Figure 2). The actual variation in lagoonal reef development however is striking, and even in areas where lagoonal reefs are prolific, such as the Tuamotus, there are examples where reefs are completely absent (Adjeroud et al., 2000; Paulay and Kerr, 2001).

### Patches, knolls, and pinnacles

Lagoons with significant reef development show two main types of subcircular structures, patch reefs and knolls. Patch reefs reach mean sea level and rise from substrates <20 m deep; where the substrate is deeper, they are termed pinnacles. Knolls are submerged reef patches but can also develop into pinnacles where they have >20 m relief (Stoddart, 1969). Patches, knolls, and pinnacles can develop in a dispersed pattern or can become connected to form linear ridges with various arrangements (e.g., Maxwell, 1968; Hopley, 1982). Dispersed patches or knolls have a density continuum from widely spaced to a point where they connect with

**Geomorphic Zonation, Figure 1** Geomorphic zonation of rough-water reefs. Both swell- and trade-wind-dominated reefs develop five standard reef zones: lagoon, reef flat, reef front, reef slope, and fore reef (not shown). These zones are delineated by simple slope breaks: the sand slope between lagoon and reef flat, the reef crest between the reef flat and reef front, the shelf break between the reef front and reef slope, and the break between the subvertical lower slope and the talus cones of the fore-reef sediment. These standard zones are divided into several widely occurring subzones, which vary with respect to margin orientation, area, and region. Images copyright of Google Earth, DigitalGlobe and GeoEye, 2010.

neighbors (Figure 2). Connected patches or knolls can further develop into ridges with sinuous, stellate, or reticulate arrangements, with the latter closing off distinct areas of deeper water, producing a cellular pattern of reef development. This cellular structure develops at various scales and can produce cells as large as 1,000 m in diameter (Figure 3).

Many lagoonal reefs have diverse coral assemblages, which can develop a distinctive windward/leeward as well as depth zonation (Wells, 1957). In Tikehau, for example, emergent patch reefs are topped by skeletal sand and cobble-sized coral gravel. The windward side has large head corals of 6 m, and leeward and deeper sides are covered by branching acroporids to depths of 15 m

(Intes and Caillart, 1994). In addition, there can be lateral gradients in coral zonation within individual lagoons as a consequence of various environmental gradients (Paulay and Kerr, 2001).

An obvious control on lagoonal reef development is the degree of water exchange with the open ocean. During World War II, causeway construction blocked spillways over reef flats and isolated lagoonal sections, causing mass mortality of corals (Maragos, 1993). This led to the realization that a dominant exchange mechanism was related to reef flat currents driven by wave setup and not necessarily to tidal exchange (Atkinson et al., 1981; Andrews and Pickard, 1990). This has been most clearly demonstrated by Callaghan et al. (2006), who showed that during most

**Geomorphic Zonation, Figure 2** Lagoonal reef development showing the varying arrangements and densities of patch reefs (emergent) and knolls (submerged). Images copyright of Google Earth, DigitalGlobe and GeoEye, 2010.

**Geomorphic Zonation, Figure 3** Reticulate reef development in lagoons shown at the same scale to emphasize the varying scales of cells enclosed by reticulate networks. In the case of Houtman-Abrolhos, subsurface data show that the networks are the result of coral growth during the Holocene. Images copyright of Google Earth, DigitalGlobe and GeoEye, 2010.

of the tidal cycle, incident wave energy on the windward margin pumps water onto reef flat and into the lagoon, while water exits over the leeward reef flat and through channels. Wave pumping causes lagoon water levels to remain above the ocean at all tidal phases and to rise significantly during periods of enhanced wave activity (see also Kraines et al., 1999). As a consequence, exchange is directly related to the proportion of reef flat that is submerged or dissected by channels and, where tidal channels are narrow or absent, island formation and sediment deposition on the reef flat can play a key role (Kench and Mclean, 2004). The impact of water exchange and wave pumping on lagoonal reef development has been clearly illustrated in the Tuamotus, where Adjeroud et al. (2000) reported that reef pinnacles were more abundant and diverse in bigger atolls, which had either large channels or a high proportion of submerged reef flat. Conversely, they found that smaller atolls with reduced exchange due to reef-flat island formation were typified by low pinnacle abundance and diversity.

### Cellular reefs

Reef development in lagoons can also be self-limiting due to a negative feedback between growth and circulation. For example, prolific development of pinnacles in protected lagoonal areas of the Houtman Abrolhos reef complex, off the western Australian coast, has produced a cellular reef pattern, as shown in Figure 3 (Collins et al., 1996; Wyrwoll et al., 2006). The reef tops have a dense cover of branching acroporids, which only extend 7–10 m down the steep walls of the cells. In some areas, the walls overhang and show collapse scars, which expose open frameworks of the same corals; the floors of the cells are between 10- and 30-m deep and covered with a thick skeletal sand and branch-coral gravel. Their water columns are stagnant and stratified and do not support coral growth below 10 m. Drill cores and seismic data confirm that these cellular reefs are composed of branching acroporid frameworks that developed during the last 7–10 ka over a flat Pleistocene reef terrace at ~40-m depth (Collins et al., 1996; Wyrwoll et al., 2006). These studies in the Houtman-Abrolhos show that the prolific growth of branching acroporids has led to the coalescence of isolated pinnacles into reticulate structures that have enclosed deeper cells, causing restricted circulation and self-limitation of coral growth. Reticulate and cellular reef development is therefore one of the several examples of self-organization in coral reefs and is an emergent property of the synergy between rapid lagoonal reef growth and circulation.

### Formation of lagoonal reefs

The development of lagoonal reefs, particularly cellular reef forms, has been persistently linked to antecedent karst due to its similarity to polygonal and cockpit-cone forms that develop in humid tropical karst terrains (MacNeill, 1954; Purdy, 1974; Purkis, 2010). However, as alluded to above, drilling and seismic profiling has consistently

shown that reef forms are growth induced, either developing from scratch during the present interglacial or continuing atop development that took place during previous interglacial stages (Harvey and Hopley, 1981; Hopley, 1982; Smith et al., 1998). On Cocos-Keeling, seismic data collected by Searle (1994) showed that the modern reticulate reef development was largely growth induced but was influenced by a combination of fossil reef growth as well as karst-induced collapse structures in the underlying substrate. In other areas, positive relief provided by previous episodes of interglacial reef growth has likely played a negative role in modern lagoonal reef development. For instance, the rims of Pacific atolls are often multigenerational reef structures, which developed during previous interglacials (e.g., Szabo et al., 1985); where these rims are continuous, they must have prevented lagoonal reef development for significant time intervals until the sea level overtopped them and initiated their modern structure ~8 ka ago. This delay in development may explain the anomalous paucity of reefs in some of the deeper modern atoll lagoons.

For other forms of lagoonal reef development however, antecedent substrates have provided little to no guidance for subsequent events. On John Brewer Reef on the Great Barrier Reef (GBR), Walbran (1994) obtained seismic profiles showing that both lagoonal patch reefs and the reef rim are underlain by a flat Pleistocene surface at 20-m depth. The same was also found at Heron and Sykes reefs in the Capricorn Group by Smith et al. (1998) and in the Houtman-Abrolhos reef complex by Collins et al. (1996). Modern reef growth in lagoons and other zones is clearly capable of generating its own structures with little help from antecedent templates of any kind.

### Reef flat

In contrast to the high-relief patches and pinnacles of the lagoon, reef flats are remarkably level surfaces and their low-tide elevation varies little for hundreds of meters. If there is any gradient at all, it tends to slope back from the outer reef flat toward the inner, and its lagoonal margin water depths are no more than 1–3 m. In the absence of islands and storm ramparts, the width of open reef flats in atoll groups such as the Marshalls and Tuvalu is between 500 and 1,000 m, but exceeds this in the Tuamotus and Maldives where flats with widths of 2,000 m are common. The presence of islands and storm ramparts however tends to significantly reduce reef-flat width by impeding sediment transport into the lagoon. As recognized by Hopley (1982), open reef flats consist of two common subzones: an outer “living zone” composed of an algal rim and a coral algal flat and an inner sand zone mantled by thin sheets of shifting sediment (Figure 1).

### Algal rims

Algal rims are usually less than 50-m wide and form the highest part of the reef flat. Two types of algal rim are

common and have been described from the Marshalls, Tuamotus, Tonga, and the southern Maldives (Tracy et al., 1948; Ladd et al., 1950; Wells, 1951; Newell, 1954; Wells, 1957; Stoddart, 1966; Nunn, 1993). The first type is an elevated  $\sim 1$ -m-high ridge (above mean low water) fronting the most exposed reef sections, normally associated with islands (ridges as high as 2.5 m have been reported from the southern Tuamotus where storm swell is severe; Salvat and Salvat, 1992). This high ridge type is commonly dissected by surge channels, 1-m wide and as much as 3-m deep, which are inshore extensions of reef-front grooves that have been narrowed by corallines (Figure 4). These channels extend back into the reef flat for 30–100 m and drain water pumped onto the flat under large swells or strong trade wind conditions. The channels can become completely roofed over and develop blow-holes surrounded by terraced coralline mounds that rise to as much as 1 m above the surrounding reef flat. The regular spacing of channels divides the algal ridge into buttresses, which form the heads of reef-front spurs (Tracey et al., 1948). The second type of algal rim develops on open reef flats and consists of a broader arch that rises less than 0.5 m but is not dissected by surge channels. Less commonly, rims consist of groups of pillars, piers, or buttresses that have been roofed over by corallines to form room-and-pillar structures (Tracey et al., 1948). Sheltered pockets and caverns in these complex structures can be capacious and may support limited coral communities. But in general, algal rim substrates are dominated by crustose corallines, particularly *Porolithon onkoides*, which requires continuous disturbance from wave surge to prevent competitive exclusion by fleshy algae (Littler and Doty, 1975). General rates of accretion of this coralline have been measured up to 10 mm/year (Steneck, 1986; Adey and Vassar, 1975), but these are clearly sufficient to build and maintain algal rims.

### Coralgal flat

A good proportion of the reef-flat zone is covered by a coralgal flat, which is an intertidal platform composed mostly of coral gravel, crustose corallines, and scattered corals. Coral cover tends to rapidly diminish away from the rim due to the increasing temperature and salinity variations in the shallow waters of the reef-flat interior (Wells, 1951). The highest coral cover is usually found in a broad trough developed immediately behind the low algal mound type along open flats (Wells, 1957). Here luxuriant patches of coral cover 50% of the surface and develop up to low tide. Between corals, the gravel substrate is stabilized by crustose corallines to form a smooth pavement. In front of islands, where there is less coral cover, the trough is clearly seen to be crossed by rimmed, partially roofed, or filled surge channels whose spacing reflects that of the reef-front grooves (Figure 4). Behind the trough is a largely barren surface covered only by a few centimeters of water at low tide. In places, several generations of eroded algal-ridge remnants protrude above the flat

**Geomorphic Zonation, Figure 4** Reef flats forming in front of islands, showing algal ridges, back-ridge troughs cut by surge channels, and the coralgal zone. Surge channels align with reef-front grooves and provide evidence of reef-flat progradation. In the Marshalls, this has occurred in jumps producing wide troughs. Images copyright of Google Earth, DigitalGlobe and GeoEye, 2010.

surface by as much as 1 m and clearly represent former positions of the algal rim (Ladd et al., 1950; Scoffin et al., 1985). Also protruding are boulders of coral framework eroded from the reef front and thrown up onto the reef flat during cyclones. These become welded to its surface by corallines and often develop an intertidal notch produced by intense bioerosion (Stoddart, 1969).

On other swell-dominated reefs, troughs are absent and the coralgal flat behind the rim consists of a very distinctive striated zone, especially in areas with high tidal ranges such as the GBR and western Indian Ocean. This consists of elongate strips of reef flat consolidated by corallines, sometimes colonized by corals, and separated by furrows of unconsolidated skeletal sand and gravel, which deepen and widen inshore (Hopley, 1982). Although coral cover varies, the furrows are persistent features, which can extend across the entire coralgal zone. At Mayotte, sand and gravel stripes clearly continue in alignment with the reef-front spur and groove, and have a height differential of 10–50 cm. At Mahé in the Seychelles, 2–3-m-high stabilized gravel ridges narrow inshore and are separated by 1–2-m-deep furrows, which widen and deepen inshore (Guilcher, 1988).

### Sand flat

The innermost sides of open reef flats, adjacent to the lagoon, are dominated by shifting sand that is either washed back from the seaward rim or, when winds switch direction during storms or monsoons, from the lagoon itself. The predominant movement of sediment in this zone occurs during tropical cyclones when large amounts of sand covering islands in the reef-front reservoir is remobilized and deposited as spill-over lobes, which prograde into the lagoon, forming a distinctive sand slope. This general sediment movement into the lagoon is interrupted by islands, which provide shelter from sedimentation and foster patch-reef development along this boundary. These patches can become well developed and form a linear reef with a steep lagoon-side scarp.

### Islands and storm deposits

Low-lying sand islands, and their associated channels (hoas) and gravel ramparts, constitute a large proportion of swell-dominated reef flats and form features which are dynamic in both space and time. Although these features are formed by a combination of storm and fairweather processes (Kench and Brander, 2006), storms assume a greater importance because they generate gravel through the destruction of corals, remobilize inactive sediment deposits on islands and in sub-wavebase reservoirs, and provide a continuous force on geological timescales. For these reasons, storms likely play a major role in initiating island formation and causing major subsequent changes (Baines et al., 1974; Bayliss-Smith, 1988). Reports of the impacts of tropical cyclones indicate that, in addition to erosion, three kinds of reef-flat deposit are common: outer-flat gravel bars, coastal ramparts along

existing islands, and aerially extensive gravel sheets over both the flat and islands (McKee, 1959; Blumenstock, 1961; Baines et al., 1974). The outer-flat gravel bars are composed of cobble to boulder-sized coral clasts, which are eroded from the reef front and typically deposited 20–30 m inshore from the algal rim. Under fairweather conditions, these gravel bars rapidly migrate inshore and are eventually left as marine cemented lenses of gravel spread out over the reef flat ~100 m from the outer rim; these are known as conglomerate platforms (Hopley, 1982). Such immobile lenses commonly provide a locus for subsequent sedimentation, and storms can add extensive shore-attached gravel ramparts for considerable distances along and between platforms (Baines et al., 1974). However, the most volumetrically important reef-flat deposits consist of thin but aerially extensive sheets of finer-grained cobble to pebble gravels that can become rapidly stabilized either in island settings by marine vadose cements to form “cay rock,” or on open reef flats themselves by crustose corallines (Newell and Bloom, 1970; Marshall and Jacobson, 1985). Successive deposition and cementation of gravel lenses and sheets can produce island platforms that reach 2 m or more above present mean sea level. Dating of these platforms in several areas has yielded anomalously old ages and, as a result, it has been claimed that they represent widespread reef-flat development during a regionally higher mid-Holocene sea level (e.g., Dickinson, 2004) despite the fact that clasts in these deposits have large age ranges (e.g., Scoffin et al., 1985).

### Formation of reef flats

The paucity of active coral growth and the flatness and low-tide elevation of many Indo-Pacific reef flats have been a continued source of confusion and, as alluded to, the age and origin of gravel deposits have provoked particular controversy (e.g., Newell and Bloom, 1970). A persistent idea is that reef flats have been eroded to their present low-tide level by a slight fall in regional sea level over the last several 1,000 years (e.g., Cloud, 1952). A variation of this has been advocated by Pirazzoli and Montaggioni (1988) and Woodroffe (2008), who suggested that the relative sea-level fall during past few millennia has produced many emergent reef flats, which are developed at elevations too high to be suitable for coral growth. This implies that reef flats were constructed by coral framework prior to the inferred sea-level fall; yet, drill cores through reef flats consistently show that they are not composed of thick framework but of detrital deposits (Henny et al., 1974; Marshall and Jacobson, 1985). Hence, the present reef-flat surface is a reflection of its interior, and an absence of corals and low-tide elevation does not require an erosional explanation. In addition, elevation data used to infer higher sea level have not accounted for elevated water levels on reef flats due to wave pumping and ponding of water behind storm ramparts, and elevations used from relict algal ridges are

commonly no higher than their modern counterparts. And even where they are, possible changes in wave climate in controlling their elevation rather than sea level are not taken into account. Moreover, in all of the reef-flat studies claiming regional sea-level highstands, the error range of the sea-level indicator is the same magnitude as the sea-level change itself (Woodroffe and Horton, 2005). Thus, claims that modern reef flats are somehow palimpsest and have been modified by falling sea level lack adequate support.

Other analyses of reef-flat form and zonation have assumed that flats did not develop until reefs caught up with sea level, despite the fact that the evidence for reef catch-up in most areas is equivocal due to inadequate core coverage (Blanchon and Blakeway, 2003). For example, Hopley (1982) proposed a retrogressive model of reef-flat development on the Great Barrier Reef in which presumed catch-up reefs progressively developed a zoned reef flat through time as reef framework and sediment migrated into the lagoon. A prediction of this hypothesis is that deposits should get younger toward the lagoon; yet, drill cores consistently show the opposite, with reef-flat ages increasing toward the lagoon in almost all the areas studied in sufficient detail (Easton and Olson, 1976; Pirazzoli et al., 1987; Randall and Siegrist, 1988; Takahashi et al., 1988; Kan et al., 1997a; Scoffin and Le Tissier, 1988; Woodroffe et al., 2000).

This widely documented pattern of inshore reef-flat ageing is more consistent with progradation, whereby the algal rim builds seaward out over the reef front through time (Ladd et al., 1950; Pirazzoli et al., 1987). Indeed, such a pattern would not only explain why reef flats are flat, with no space for framework accretion, but it would also account for many of their morphological features. For example, the widespread occurrence of back-rim troughs and surge channels extending 100 m or more into the reef flat interior is a key indication of this process (Figure 4). Imagery from the Marshall Islands in particular indicate that back-rim troughs represent shallow spur and groove that were abandoned due to algal-rim development along their leading edges (see Bikini and Rongelap, in Figure 4). The jump in the rim position to the spur front consequently left a shallow trough between the old and new rim that provided space for coral growth. In many areas, coral growth and gravel deposition rapidly filled this trough and only surge channels remain as evidence of its existence. In this way, reef flats can prograde rapidly and produce an extensive flat surface devoid of coral growth that is punctuated only by abandoned algal rims and boulder thrown up during storms. Why algal rims are periodically abandoned and jump seaward is related to the dynamics of spur-and-groove development, which is outlined below.

### Reef front

The reef front zone extends from the reef crest to the shelf break which, in many areas, occurs between depths of

20 and 50 m. This shallow zone is perhaps the most distinctive of all reef environments and consists of narrow annular subzones, which show remarkable concordance between regions. As shown in Figure 1, reef fronts on swell- and trade-dominated reefs generally consist of three common subzones: a shallow spur-and-groove zone, which extends down to a mid-shelf slope break around 10 m, followed by a relatively low-gradient sand terrace at 15–25 m, which passes into a chute and buttress zone developed over the shelf break and down the reef slope. In all of these subzones, reef development is molded by wave scour during both fairweather and storms and forms a characteristic cross-shelf sequence of elongate spur systems. In shallow water, scour is also responsible for sculpturing exposed bedrock surfaces into ridges and furrows, with ridges becoming enhanced by coral colonization (Allen, 1982; Blanchon and Jones, 1995). Unfortunately, due to the rigors of collecting data in such wave-swept areas, reef development in these subzones is poorly known and core data exists only for the greater Caribbean with no reports for any Indo-Pacific reef fronts.

### Spur and groove

Spur and groove is a general term for regularly spaced arrays of buttresses and channels, which extend across the shelf (Figure 5). Two types of shallow spur and groove are common: one dominated by coralline algae and the other by corals. These systems are not mutually exclusive however and their distribution and form is controlled by wave energy (Munk and Sargent, 1954; Roberts, 1974; Sheppard, 1982; Blanchon and Jones, 1997; Storlazzi et al., 2003). Both coral and algal spurs can be present along the same high-energy swell-dominated reef front: a shallow high-energy surf-zone system, dominated by crustose coralline algae (see Ujelang and Oeno, Figure 5), and a lower-energy coral-dominated system that either develops downslope in slightly deeper waters (see Nonouti and Diego-Garcia, in Figure 5) or in an equivalent position along the leeward margin (Sheppard, 1981; Glynn, 1996). Furthermore, the frequency of spurs shows a correlation with water depth (and hence wave energy): surf-zone systems have a spacing of one spur every 6–10 m, whereas in deeper-water systems, such as the chute and buttress zone (see below), spurs are spaced every 30 m or more, largely as a result of greater spur widths and wavelengths (Blanchon and Jones, 1997; Storlazzi et al., 2003). Surf-zone spur systems extend seaward from the reef crest for 50–100 m dependent upon the shelf slope, whereas deeper water spur systems can be more extensive, and submerged terraces can be covered by coral spurs for several kilometers.

In high-energy swell-affected reefs, shallow spur-and-groove systems are dominated by coralline algae and extend seaward from algal rims parallel to wave orthogonals (Munk and Sargent, 1954; Sargent and Austin, 1954). Spurs are commonly 4–8-m wide and have steep, sometimes overhanging, sides; intervening grooves are

**Geomorphic Zonation, Figure 5** Shallow reef-front spur and groove. In the cases of Nonouti and Diego-Garcia, algal spurs pass into coral-covered spurs further downslope, whereas in the cases of Ujelang and Oeno, algal spurs pass into a bedrock sculptured into ridges and furrows by storm-wave scour. Images copyright of Google Earth, DigitalGlobe and GeoEye, 2010.

1–3-m wide and 2–8-m deep and are commonly floored with coral gravel that is moved only during storms. At their seaward ends, spurs have an amplitude of 5–8 m and terminate in waters 5–10-m deep (Tracey et al., 1948; Ladd et al., 1950; Cloud, 1952; Newell, 1956; MacNeil, 1972; Pichon, 1978; Sheppard, 1981; Intes and Caillart, 1994; Glynn et al., 1996). Spurs narrow seaward and can be straight-sided with a smooth surface or more irregular and covered by protuberances (Figures 4 and 5). Near surf base, the surface of spurs are covered only by patches of slow-growing crustose corallines or fleshy algal turfs, whereas below it small corals with reptant growth forms are common between the corallines (e.g., Intes and Caillart, 1992; Glynn et al., 1996). In the Marshall Islands, Munk and Sargent (1954) found that the grooves showed a bimodal frequency distribution that corresponded to the northeast trades and, during the summer, to swell from the southeast trades of the southern hemisphere. Also their depth and length were proportional to the wave period, so that the wave up-rush traveled the length of the surge channel and impeded up-rush of the next wave on its return. This, together with friction along the sides of the channels, was sufficient to dissipate wave energy and make spur and groove an effective natural breakwater.

In lower energy trade-wind reefs protected from swells, spur systems also form parallel to wave orthogonals but are covered by corals and composed of coral framework and extend seaward from gravel-dominated rims (Shinn et al., 1981, 1982; Blanchon and Jones, 1997). The fundamental difference between algal- and coral-spur systems is simply that coral spurs lack a thick, extensive cover of corallines, and this allows storms to regularly prune their coral cover and supply the crest and flat with copious amounts of coral gravel (Blanchon and Jones, 1995, 1997). Coral-line algae only play a significant role in stabilizing and binding this gravel (e.g., Macintyre et al., 2001).

### Formation of spur and grooves

Although the development of algal spur systems is poorly known due to the absence of core data, limited excavations and drilling on the outer reef flat support a growth origin (Henny et al., 1974; Marshall and Jacobson, 1985; Szabo et al., 1985; Glynn et al., 1996; Kan et al., 1997b). At Clipperton Atoll in the eastern Pacific, for example, shallow excavations into the ends and sides of algal spurs revealed a 1-m-thick base of *Pocillopora* sp. framework overgrown by crustose corallines, which was overlain in places by similarly overgrown colonies of massive *Porites lobata* (Glynn et al., 1996). This same *Pocillopora*–*Porites* assemblage formed coral spurs directly downslope in front of the algal spurs, indicating a developmental progression from intermittent coral growth, storm disturbance, and coralline overgrowth through time. This process is supported by several observations. First, reptant colonies of *Pocillopora* are scattered over the deeper parts of the algal spurs between 3 and 7 m, which indicates that corals can grow on spurs up to the base of the surf zone

(Sheppard, 1982; Intes and Calliart, 1994). Second, coral growth in front of the algal spurs is largely dead and overgrown with crustose corallines (Glynn et al., 1996), indicating that the framework in these areas is rapidly stabilized and might be more resistant to removal or pruning during storms. These two observations imply that the distal spur ends have the highest potential for lateral and vertical accretion, which can proceed rapidly until they intersect with surf base at  $\sim 3$  m. From there, thick crusts of *Porolithon onkoides*, previously excluded due to fleshy algal overgrowth and surface grazing, causes a continued rapid accretion into the surf zone, leading to the upgrowth of a new algal ridge (Tracey et al., 1948). In this way, the process of distal spur upgrowth could not only facilitate spur development but also might drive reef-flat progradation over time. It also explains the problematic occurrence of double reef crests in several areas (Hopley, 1982; Guilcher, 1988).

More subsurface data is available for coral spur systems – mostly those from the greater Caribbean (Shinn 1963; Shinn et al., 1982a, b). In both Florida and Belize, for example, blasting and drilling indicate that shallow spur systems are composed of interlocking branched colonies of the surf-zone coral *Acropora palmata*, thickly encrusted by corallines (Shinn, 1963). Although this resembles the structure of algal spurs, the basal age of the coral spurs shows that they are older at their seaward end and get younger toward the reef crest, suggesting that they retrograded over their own back-reef deposits as sea level rose (Shinn et al., 1982a). Although the age structure of algal spurs is still unknown, ridge progradation indicates that spurs develop in the opposite direction and prograde seaward. If confirmed, this would be a major difference between these two types of spur system.

### Mid-shelf scarp and sand terrace

The area downslope from the shallow spur-and-groove system in water  $\sim 8$ –10-m deep, consists of a gently sloping bedrock terrace, which is either covered with coral spurs or is a bare rock ground, that has been sculptured by wave scour into low ridges and shallow furrows (e.g., Blanchon and Jones, 1995). This upper rock terrace is commonly terminated by a mid-shelf slope break before flattening out again into a lower sand-covered terrace, which extends out to the shelf edge (Figures 1 and 6). Both the slope break and sand terrace are frequently traversed by a system of widely spaced coral spurs between which thick deposits of skeletal sand and gravel accumulate. Being below the fairweather wave base, this sediment is only mobilized during storms, which ensures that the coral growth survives only on the elevated spurs. Coral gravel deposited at the end of the spurs is sheltered to some extent from wave scour, and subsequent colonization by corals during post-storm conditions ensures that spurs maintain their alignment with wave orthogonals and gradually extend out across the shelf. Where the sand terrace is

**Geomorphic Zonation, Figure 6** Reef-front mid-shelf scarp and sand terrace (or “10-fathom” terrace). Scarp best seen where reef growth is limited and commonly has an intertidal notch (as at Grand Cayman). Their presence around uplifting islands, such as Barbados, indicates an early Holocene sea-level origin. Images copyright of Google Earth, DigitalGlobe and GeoEye, 2010.

narrow, less sediment accumulates and more coral development is possible. Conversely, where the terrace is wide, a larger sand reservoir can prohibit spur development completely.

The sand terrace is a prominent feature seen in imagery from all oceans (Figure 6) and has been widely reported as the “ten fathom” terrace (Emery, 1961; Garrison and McMaster, 1966). Where it is not covered by excessive reef development, the terrace has been documented in roughly the same  $20 \pm 5$  m depth range from the following areas: the Marshall Islands (Tracy et al., 1948; Emery et al., 1954), the Caroline Islands (Tracey, 1968), the Tuamotus and Society Islands (Newell, 1956; Chevalier et al., 1968), Johnson Island in the central Pacific (Keating, 1985), Clipperton in the east Pacific (Glynn et al., 1996), the Solomon Islands (Stoddart, 1969), the Cocos-Keeling Islands and the Maldives in the Indian Ocean (Williams, 1994; Bianchi et al., 1997), the Bahamas and Caymans in the Caribbean (Blanchon and Jones, 1995; Newell, 1951), and Bermuda in the Atlantic (Stanley and Swift, 1968). In short, the slope break and the sand-covered 10-fathom terrace are ubiquitous geomorphological features and clearly represent the terrace and riser (cliff) of an abandoned submerged shoreline (Blanchon and Jones, 1995).

#### Formation of terrace-scarp reef-front features

Hopley (1982) argued that similar terraces on the Great Barrier Reef represented common levels of reef growth during glacial interstadials. A similar incremental explanation was suggested by Paulay and McEdward (1990), who simulated reef development over the last 125 ka. Both dismissed marine erosion as insignificant based on micro-erosion-meter measurements of fairweather coastal erosion (Spencer, 1985). However, mathematical modeling using more realistic erosion rates has demonstrated that marine planation is capable of producing terraces in all but the most resistant lithologies in less than 5 ka (Trenhaile, 1989). Furthermore, the presence of the sand terrace around islands with a history of uplift during the Pleistocene such as Barbados in the Caribbean and raised atolls in the Vanuatu chain, south Pacific, indicates that it must have developed during the postglacial rise in sea level (Blanchon and Jones, 1995). In fact, several drowned early Holocene breakwater reefs have been discovered associated with the terrace (Lighty et al., 1978; Blanchon et al., 2002). The crest of an 8-ka old reef was discovered around Grand Cayman along the inner edge of the terrace at a depth of  $\sim 20$  m, and its elevation corresponded with the position of an intertidal notch preserved in the mid-shelf scarp on the other side of the island (Blanchon et al., 2002). A correlation with similar elevations of drowned breakwater reefs, notches, and terraces developed around other islands in the Caribbean led Blanchon et al. (2002) to propose that these reefs and their shorelines were drowned by a meltwater pulse (Mwp-1c) during the early Holocene that was associated with the final

disintegration of the Laurentide Ice Sheet. The timing of this pulse is also consistent with further discoveries of drowned reefs in the Gulf of Carpentaria (Harris et al., 2008) and has been confirmed in several other non-reefal records of early Holocene sea level (e.g., Hijima and Cohen, 2010).

Much of the emphasis in these various explanations has been placed on the terrace-forming process. Yet, it is difficult to prove from these data alone if the terrace resulted from marine erosion or from incremental reef accretion. Also, it is no surprise that the terrace elevation differs slightly between reefs, given the variation in sediment and reef deposition during the Holocene; however, neither of these factors is particularly important to explain. This is because the notched scarp at the head of the terrace clearly shows it formed the shoreline behind reef crests that drowned during the 8-ka meltwater pulse. As a consequence, the presence of this scarp separating terraces in reef-front zones in other areas indicates that they too were subject to same shoreline development  $\sim 8$  ka ago. The surprising thing is that the notched scarp survived shoreface erosion during the subsequent sea-level rise and went on to influence reef development (Blanchon and Jones, 1995). Indeed, the preservation of notched scarps and abandoned reef crests in different oceans is testament to the sudden acceleration of sea level during that 8-ka meltwater pulse. It also explains why modern breakwater reef development in these areas did not start until after that 8-ka event (Blanchon et al., 2002).

#### Reef slope

In many areas, the reef slope is the most poorly known of the major geomorphic zones. It represents the outermost zone of reef construction and can be arbitrarily divided into two subzones: an upper subzone from the shelf break to the limit of effective coral-framework development at  $\sim 60$  m, and a lower subzone down to 120 m or more that may be dominated by a sciaphyllic framework of sclerospores, coralline algae, and microbialites. The geomorphology of this lower subzone has been modified by reef accretion but still bears a strong imprint of sea-level change during the last glacial–interglacial hemicycle (e.g., Anderson, 1998).

#### Shelf-edge chute and buttress (shelf-edge reefs)

Slope breaks associated with the mid-shelf scarp and shelf edge are often sites of preferential reef development because sediment bypasses these steeper areas on its way to depocenters on sand terrace and at the base of the reef slope, respectively; this is known as the “edge effect” (Porter, 1972). The shelf-edge site in particular is commonly associated with spectacular reef development (as shown in Figures 1 and 7), which has been described from various locations as either, sill reefs, shelf-edge reefs, or mesophotic reef systems (Goreau and Goreau, 1973; Burke, 1982; Blanchon and Jones, 1997; Lesser et al., 2009). This reef system develops from the brow of the

**Geomorphic Zonation, Figure 7** Submerged shelf-edge reef development. Accretion produces an array of buttresses with spurs that extend back over the sand terrace (see Grand Cayman) and down subvertical walls covered by platy corals to 60-m depth. Below that, platy coral cover is reduced and sclerosponges become more abundant. Images copyright of Google Earth, DigitalGlobe and GeoEye, 2010.

shelf edge at  $\sim 25$  m down the reef slope to  $\sim 60$  m and can extend laterally for tens of kilometers (e.g., Burke, 1982; Blanchon and Jones, 1997). These extensive shelf-edge reefs have generally been considered to be part of the main “reef complex” and have not been widely considered to be separate entities. However, several observations suggest otherwise: First, shelf-edge reefs commonly form along margins where breakwater reefs are absent (Blanchon and Jones, 1997). Second, they have been reported along the edge of much wider shelves where they are widely separated from breakwater reef complexes (e.g., Harris and Davies, 1989). In most areas however, these structures are juxtaposed along narrow shelves and, although influenced by similar processes, respond independently, producing distinctive reef architectures and biotopes (Figure 7).

One of the few characterizations of a shelf-edge reef system has come from the Caribbean Island of Grand Cayman (Blanchon and Jones, 1997). There, shelf-edge reef development extends around the full perimeter of the island (87 km) and forms an array of coral-covered buttresses separated by sediment floored chutes and canyons, which are aligned perpendicular to the shore (Figures 6 and 7). Individual buttresses consist of three elements: a subvertical front wall colonized by platy coral that plunges over the shelf edge; a dome-shaped crown covered by large head corals; and a shoreward-projecting spur covered by branching corals. On windward margins, these buttresses have an amplitude of about 10 m and their crowns rise to a depth of  $\sim 22$  m. In the most-exposed shelf sections, spurs have a frequency of one every 27 m and extend across the full width of the sand terrace to merge with the spur system covering the mid-shelf scarp. Along the less-exposed sections however, the spur length decreases and their frequency is reduced to one spur every 75 m. These trends also exist along more protected margins, and the spur frequency decreases in response to shelter from the ambient wave field. In addition, crowns rise into waters of 16 m and buttress amplitudes are reduced to  $\sim 7$  m (Blanchon and Jones, 1997). Along the leeward margin, buttresses merge to form an almost continuous sill reef dominated by branching corals and little spur development. This sill rises into waters as shallow as 12 m.

#### Formation of shelf-edge chutes and buttresses

Roberts (1974) found a correlation between shelf-edge buttress-spur orientation and vectorial properties of the wave field affecting Grand Cayman. From this, he conjectured that these deep-water spur systems had inherited the form of shallow spur-and-groove structures that were drowned as the sea level rose during the Holocene (Roberts et al., 1975). This was contested by Blanchon and Jones (1997), who showed that the lower frequency and more widespread distribution of shelf-edge spurs was inconsistent with this inheritance hypothesis. Instead, they suggested that the covariance between buttress area, amplitude, spur frequency, and local margin

orientation was more consistent with the varying destructive intensity of hurricane wave scour and approach angle (Blanchon and Jones, 1997; Blanchon, 1997). In other words, these shelf-edge reefs were produced by significant reef accretion in deeper waters. Although no drilling has yet proved this around Grand Cayman, cores from an extensive shelf-edge reef off Carrie Bow Cay, on the Belize Barrier reef, recovered an 11.6-m-thick section of domal and branching framework that developed over the last 5 ka (Macintyre et al., 1981). Similarly, 9 m of domal framework that had developed in the last 7 ka was encountered on a shelf-edge reef off the south coast of Barbados (Fairbanks, 1989). Off St. Croix, horizontal drilling into the front wall of a shelf-edge reef buttress by Hubbard et al. (1985) recovered 6 m of lateral accretion consisting of alternating detritus and domal framework. These thicknesses of framework are clearly sufficient to account for the amplitude of the shelf-edge reef buttresses and spurs in these areas and therefore support the contention that the shelf-edge reefs are independent structures controlled by ambient environmental processes (Macintyre et al., 1981; Blanchon and Jones, 1997).

### Lower reef slope

The upper section of the reef slope to ~60-m depth is dominated by a cover of platy corals associated with shelf-edge reef development; however, in the lower section of the slope below 60 m, this coral coverage declines rapidly, and by 100 m, generally forms a cover of less than 1%. In areas investigated by submersibles, this lower slope usually consists of a near-vertical wall with an irregular surface consisting of discontinuous, sediment-draped ledges and blind caves dissected by vertical chutes and gullies (Ginsburg et al., 1991; Grammer and Ginsburg, 1992). This irregular substrate is colonized by a sciaphyllid assemblage of sclerospoges, crustose coralline algae, microbialites, and platy corals, and their zonation and distribution are controlled by the light gradient, falling sediment from the shelf above, and the margin orientation (Goreau and Land, 1974; Land and Moore, 1977; Sheppard, 1982; Colin et al., 1986; Liddell and Ohlhorst, 1988; Ginsburg et al., 1991; Lesser et al., 2009). By far, the most thoroughly investigated lower reef slope is that along the north coast of Jamaica (Hartman and Goreau, 1970; Goreau and Land, 1974; Lang et al., 1975; Land and Moore, 1977; Liddell and Ohlhorst, 1988). In this area, the depth zone between 60 and 100 m consists of a variable cover of sclerospoges, with reports ranging from 7% to 25% and as much as 50% on the walls and ceilings of caves. In fact, in a cluster of caves between 80 and 90 m, Lang et al. (1975) reported sclerospoges as large as 1 m in diameter. Furthermore, a half-meter-deep blast site at 105 m exposed the sclerosponge framework with interstitial skeletal sediment cemented by high-magnesian calcite (Land and Moore, 1977). Similar abundances of sclerospoges have also been reported

from the Bahamas, where Ginsburg et al. (1991) estimated a cover of 5–25% in the same depth range.

### Formation of the reef slope

There is generally a very little subsurface data available concerning the development of reef-slope environments. The tendency of modern reefal margins to form steep precipitous slopes must relate to both accretion and erosion during rapid sea-level changes during glacial–interglacial cycles. For example, Blanchon and Jones (1997) suggested that the pattern of vertical and lateral accretion in shelf-edge reefs may explain the steep precipitous upper slope development that is common in many reefal margins. However, the vertical walls of the deeper lower slope must be related to the long phases of sea-level lowstands at 125 m or more that are associated with glacial stages (Land and Moore, 1977). Although these cliffs are presently covered by coral and sclerosponge frameworks and are likely undergoing some small amount of lateral accretion (e.g., Ginsburg et al., 1991), cliff recession rates during the extended duration of glacial lowstands must have been substantial. Therefore, the basic geomorphology of these vertical substrates is likely erosional – a claim that is supported by widespread reports of giant blocks of wall rock on forereef depositional slopes.

### Summary and conclusions

Rough-water coral reefs that develop in trade-wind-, swell-, and storm-dominated seas consist of five standard geomorphic zones: a back-reef lagoon, a reef flat, a reef front, a reef slope, and a fore-reef talus apron. These zones are separated by simple slope breaks: back-reef lagoons terminate at the sandslope break, reef flats terminate at the reef-crest break, reef fronts terminate at the shelf-edge break, and reef slopes terminate at the fore-reef talus break.

In lagoons, reef development can be extensive and reefs develop as dispersed knolls or patches that commonly merge to form ridges; these in turn can connect with other ridges to form complex reticulate networks that impede water circulation and self-limit their own development. In many lagoons, water circulation is a function of wind stress and exchange with the open ocean, with the latter process being controlled by a wave-pumping mechanism over open reef flats. Atolls with large sections of open reef flats therefore have better lagoonal reef development than smaller atolls, where the exchange system is more vulnerable to blockage by island formation in space and time. Seismic data show that the lagoonal reef form and development is not, as often claimed, inherited from a karstic substrate but entirely growth induced either from simple vertical and lateral accretion during the Holocene or from compound growth over previous interglacials.

Reef flats by contrast are remarkably flat intertidal platforms that can be several kilometers wide. They consist of an algal rim, an outer coralline flat, an inner sand flat, and a variable cover of low-lying detrital islands. The algal

rim, generated by the surf-adapted coralline *Porolithon onkoides*, forms the highest part of the reef flat and consists of either an elevated ridge fronting islands along the most exposed reef sections or a lower mound along more open flats. Behind the rim is an intertidal coralgal platform, veneered by a rapidly decreasing cover of corals and an increasing proportion of coral gravel stabilized by coralline algae. In its outer part, this platform can be punctuated by one or multiple remnants of former algal ridges whose age increases inshore or by large blocks of reef framework thrown up from the reef front during storms. In addition, the coralgal flat is commonly dissected by surge channels, which extend back into the reef flat in-line with reef-front grooves. Some flats are crossed by corals organized into narrow, parallel ridges that are separated by gravel-filled furrows, which also align with reef-front grooves. These various types of coralgal flats either grade into an inner flat dominated by shifting sands or pass directly into cobble rampart-fronted islands composed of a mix of storm-lain sand and gravels that can reach 4 m or more above the surrounding flat. Although stabilized by marine and meteoric cements, these gravel islands yield clasts with a large spread of ages, suggesting that they are commonly reworked by storms.

In explanations of reef-flat development, it has been argued that elevated islands, remnant algal ridges, and the extremely flat, barren nature of reef flats are a combined result of a late Holocene regional fall in sea level, which led to erosional planation of the surface to its present level. Several authors, however, have noted that these same features are consistent with processes that are presently active with a stable sea level. In fact, many of the key features of reef flats, such as their monotonous flatness, aligned features, and remnant ridges, can be accounted for by the simple seaward progradation of the algal rim out over the reef-front spur-and-groove zone through time.

Spur-and-groove development in shallow, rough-water reefs consists of two types: one with spurs covered by crustose coralline algae and the other with spurs covered by corals. On swell-dominated reefs, algal spurs extend seaward from the algal rim parallel to wave orthogonals and form high-frequency, steep-sided spur arrays, whose length is proportional to wave energy and the gradient of the seaward shelf. Coral spurs have a similar form and frequency but develop in lower wave-energy regimes either downslope from algal spurs or in an equivalent position along the leeward margin. All subsurface evidence collected so far point to a growth origin for both spur types, with algal spurs nucleating on downslope coral growth causing a seaward progradation through time, and coral spurs developing downslope from the crest and retrograding upslope through time.

The platform downslope of the shallow spur-and-groove terminates at about -10 m in a mid-shelf slope break that commonly takes the form of a small notched scarp (where it has not been covered by coral spurs or sedimentation). This scarp forms the riser to a distinct

sand-covered terrace, known as the 10-fathom terrace, which slopes from 20 to 30 m out to the shelf edge. This 10-fathom terrace and its scarp has been reported from all oceans and even around uplifting islands such as Barbados, and has become a depocenter for sediment accumulation and reef development during the Holocene. Discoveries of several early-Holocene breakwater reefs on the terrace prove that the notched scarp and terrace couplet represents a cliffed shoreline that formed around the same time and was drowned by a meter-scale sea-level jump ~8 ka ago.

The shelf break at the terrace edge is commonly a site of extensive submerged reef development, which has produced an array of sand chutes and steep-sided buttresses that form parallel to wave orthogonals. The buttresses, which can rise to 15 m and have amplitudes of 10 m or more, extend back over the terrace as a series of tapering spurs. To seaward, the subvertical face of the buttresses extends down the reef slope to ~60 m and has a dense cover of platy corals. Covariance between buttress area, amplitude, spur frequency, and local margin orientation indicates that the architecture of these shelf-edge reefs is controlled by hurricane wave scour and approach angle. Other suggestions that they developed over drowned breakwater reefs are not supported by drilling, which shows that shelf-edge reefs have produced greater than 12 m of vertical growth and 6 m of lateral accretion in the last 5 ka.

The reef slope beneath shelf edge reefs is commonly vertical below 60 m and is covered by an assemblage of sciaphyllic sclerosponges, crustose corallines, and microbialites. Although this assemblage is actively producing framework, the morphology of the deep reef slope has been significantly influenced by cliff collapse and mass wasting during the long intervals of glacial lowstands of sea level.

The remarkable similarity of reef geomorphology and architecture between and within oceans is a clear testament to their capacity for self-organization (Hatcher, 1997; Dizon and Yap, 2006). In other words, many of the features of these large-scale structures have emerged spontaneously from ecological processes operating at smaller scales. For example, the negative feedback between the simple vertical and lateral reef accretion and water circulation has produced extensive networks of cellular reefs in many lagoonal systems. Likewise, the simple interaction between wave scour and the colonization and growth of corals and crustose coralline algae has produced well-ordered spur systems with similar spacings at both local (windward-leeward), regional (trade or swell) and inter-oceanic scales. Finally, the interaction between herbivory and coralline accretion along the seaward edge of algal spurs may be responsible for intermittent seaward advances of reef flats through time.

Perversely, many of those responsible for interpreting large-scale reef development still cling to the paradigm that modern reefs are somewhat of a geological oddity and that their form and architecture are merely

a reflection of the underlying antecedent substrate – a position that would surely have Darwin turning in his grave. Although examples do exist of this substrate control, scaling-up of the concept to entire reef systems denies abundant evidence that reefs have built impressively thick, well-structured edifices during the last 14 ka, which have maintained their breakwater position as post-glacial sea level rose 120 m or more from its glacial low-stand. An understanding of the interactions and feedbacks that control reef organization during this development is key to assessing resilience and resistance of modern reef systems in the face of human-induced global environmental change.

## GLACIAL CONTROL HYPOTHESIS

---

Tom Spencer  
 University of Cambridge, Cambridge, UK

### Synonyms

Glacial control theory

### Definition

Hypothesis developed by R. A. Daly to argue for youthful, postglacial development of atolls and barrier reefs on platforms beveled during low sea surface temperatures and sea levels of glacial periods.

### ‘Glacial control’ of coral reef development

#### Development of the hypothesis

The glacial control hypothesis, developed and defended through a series of lectures, scientific papers, and book chapters between 1910 and 1948 by R. A. Daly, was an exploration of the effects of Pleistocene climate and sea-level change on coral reef evolution and morphology. The hypothesis should be seen in the context of Nathaniel

Shaler’s (1875) argument that sea level rather than the land was subject to general movement and Eduard Suess’s development of the idea of eustatic sea-level change in the second volume (1888) of “Das Antlitz der Erde” (translated by H. B. C. Sollas and W. J. Sollas as the “Face of the Earth” in 1906). Both Suess and Murray (1879–1880) favored the idea of the wave erosion of the summits of young volcanoes as providing a suitable platform for subsequent coral growth (and see also Steers and Stoddart, 1977 for ideas on planation surfaces and reef growth by Semper, Wharton, Guppy, and Gardiner).

Daly visited Hawaii in 1909 and observed the narrowness of the encircling reefs which he inferred as an indicator of young age; he saw evidence for recent glaciation on the volcanic slopes of Mauna Kea, indicating lower glacial temperatures; and he noted the closeness of contemporary sea surface temperatures in the northern winter at Hawaii to the threshold temperature for reef growth. These observations were built into the glacial control hypothesis, first published in 1910 and reaching their full development in the Silliman lectures delivered at Yale University and published in 1934 in a book entitled “The Changing World of the Ice Age.” W. M. Davis saw Daly’s hypothesis as diametrically opposed to Darwinian subsidence theory and submitted it to sustained intellectual attack (e.g., Davis, 1918, 1919, 1923, 1928) but, as Stoddart (1973) has pointed out, Darwin was concerned with understanding large-scale reef structure, whereas Daly was more concerned with explaining reef surface morphology.

Daly’s key fact, backed up by an analysis of bathymetric charts of reef areas, was the global accordance and planar nature of atoll lagoon floors and continental shelves in the reef seas within a limited depth range of 55–90 m. He argued that during the glacial periods, sea level fell, sea surface temperatures declined, and water turbidity increased. These processes, perhaps exacerbated by increased storminess and wave attack, resulted in coral mortality, the removal of dead coral framework, and the erosion of volcanic shores no longer protected by healthy reef structures. The outcome was the production of beveled platforms on volcanic islands and older limestone basements. As sea level rose and sea surface temperatures increased with the onset of interglacial conditions, then coral growth resumed, preferentially on the platform margins (where environmental conditions were most favorable for coral growth) to result in typical atoll and barrier reef morphologies (Figure 1).

### Tests of the hypothesis

The hypothesis encompasses several elements all of which are amenable to test as a result of late twentieth/early twenty-first century developments in Quaternary science. First, what was the degree of sea-level fall during the glacial periods? Second, what was the degree of sea temperature cooling during the glacial periods? And third, how easy is it to bevel a reef structure and produce a smooth platform?

**Glacial Control Hypothesis, Figure 1** Sections illustrating aspects of the glacial control hypothesis of coral reefs. *Diagonal shading* indicates stable basement. 1: eustatic rise of sea level during the last interglacial stage giving new coral growth (in black), largely at the platform margin; 2: sea-level fall and water temperature decrease during the onset of the last glacial period, during which corals die and reefs are eroded; 3: at the Last Glacial Maximum reefs are destroyed and the bank is eroded to below the lower sea level; 4: the postglacial rise in sea level, together with a temperature increase, allows renewed coral growth (in black), particularly at the outer reef margins; 5: the present features of an atoll encircling a flat-floored lagoon. Source: Daly (1934).

Daly (1910) originally postulated a sea-level fall of 46 m at the glacial maximum which he then revised to a figure of 60–70 m, having dismissed the estimates of sea-level fall of 150 m as “excessive” (Daly, 1934, p. 165). It is now clear from drilling submerged *Acropora palmata* reefs offshore from the south coast of Barbados that sea level at the last glacial maximum (18 ka BP) was  $121 \pm 5$  m (Fairbanks, 1989).

For glacial sea surface temperature, Daly suggested a typical cooling of  $5^\circ\text{C}$ , with a maximum potential fall of  $10^\circ\text{C}$ . Quantitative reconstructions of last glacial maximum sea surface temperature, based on the microfossil and geochemical analyses of deep-sea cores, were first developed by the Climate Long-Range Investigation, Mapping, and Prediction (CLIMAP) project in the 1970s and 1980s (CLIMAP project members, 1976) and have recently been updated by the Multiproxy Approach for the Reconstruction of the Glacial Ocean Surface (MARGO) project. MARGO project members (2009) report an average mean

annual cooling at the last glacial maximum of  $1.7 \pm 1^\circ\text{C}$  for the tropical ocean between  $15^\circ\text{N}$  and  $15^\circ\text{S}$ . This can be disaggregated regionally into a cooling of  $2.9 \pm 1.3^\circ\text{C}$  in the Atlantic Ocean,  $1.4 \pm 0.7^\circ\text{C}$  in the Indian Ocean, and  $1.2 \pm 1.1^\circ\text{C}$  in the Pacific Ocean. There were, however, considerable temperature variations in the latter region: cooling of  $1\text{--}3^\circ\text{C}$  in the western Pacific Ocean warm pool, cooling of  $5\text{--}6^\circ\text{C}$  in the equatorial eastern boundary current along the Chilean coast but warming of  $1\text{--}2^\circ\text{C}$  in the subtropical gyres in both hemispheres. Daly claimed that “over wide stretches of the tropical seas the reef corals were exterminated or greatly weakened in their reef-building power” (Daly, 1934, p. 159). However, if the known falls in temperature are subtracted from the present patterns of ocean temperature isotherms for the coldest month, and the isotherm of  $20^\circ\text{C}$  is taken as the limit to effective reef growth, then the change in the area available for reef growth during the glacial periods can be illustrated (Slaymaker et al., 2009; Figure 2). This analysis shows that while Daly’s

**Glacial Control Hypothesis, Figure 2** Changing tropical ocean temperatures, Last Glacial Maximum to present, and implications for coral reef growth (from Slaymaker et al., 2009).

speculations on the magnitude of temperature fall were of the correct order of magnitude, his interpretation of their likely impact was incorrect. It was only on the very margins of the reef seas and in the area of the eastern boundary currents that sea temperature cooling was sufficient to cause a likely cessation of reef growth. Interestingly, these marginal belts were the one area where W. M. Davis was prepared to accept the occurrence of coral platforms of low-level abrasion, these being the only locations in the reef seas where cliffed volcanic island slopes can be seen on the margins of barrier reef lagoons (Davis, 1915, 1928).

Daly estimated that 50–200,000 years was available for platform abrasion and leveling in the periods of low sea level during the glaciations. This inference is broadly correct; environmental reconstructions from ice-cores and marine sediments in deep-sea cores show that lower than present sea levels have typically characterized 88,000 years of the characteristic 100,000-year long glacial–interglacial cycles of the last 500,000 years (e.g., Imbrie et al., 1993; Petit et al., 1999). While accepting that young volcanic islands were composed of erosionally resistant lava flows, Daly believed that most volcanic and coral islands were “composed of generally weak material” (Daly, 1934, p. 177) and that erosion rates of coral limestones would be comparable to the  $0.3\text{--}1.0\text{ m a}^{-1}$  retreat rates of the chalk cliffs in coastal southern England and northern France and that pyroclastic deposits and shelf sediments might be removed at rates comparable to the retreat rates of ca.  $2\text{ m a}^{-1}$  of the glacial cliffs on the UK Yorkshire coast of

the North Sea. Thus, there appeared to be no difficulty in beveling even large volcanic islands and extensive reef deposits in the time available, particularly if material had been weakened by previous phases of weathering and erosion under earlier glaciations. Recent quantitative measurements using the microerosion meter technique on shore platforms, over a range of materials and in different process environments around the world suggest, however, that erosion rates are several orders of magnitude lower than the rates used by Daly, with a mean rate of surface lowering of  $1.5\text{ mm a}^{-1}$  (Stephenson and Finlayson, 2009). Within this dataset, the erosional behavior of presently raised reef limestones provides an apt modern day analog for the reaction of reefs exposed by glacial falls in sea level. Such surfaces have been comprehensively investigated in two locations: at meso- to macrotidal Aldabra Atoll, western Indian Ocean by S. T. Trudgill (Trudgill, 1976a, b, 1983; Viles and Trudgill 1984) and at microtidal Grand Cayman Island, West Indies by T. Spencer (1985a–c). At Aldabra, mean intertidal rates of surface lowering were  $1.79\text{ mm a}^{-1}$ , varying between  $1\text{ mm a}^{-1}$  on low energy coasts to  $4\text{--}7\text{ mm a}^{-1}$  on exposed coasts. In the supratidal zone, the mean rate of subaerial erosion was  $0.26\text{ mm a}^{-1}$ . On Grand Cayman, the mean intertidal erosion rate was  $1.23\text{ mm a}^{-1}$ , varying between  $0.45$  and  $2.43\text{ mm a}^{-1}$  on reef-protected and exposed coasts, respectively (with bioprotection reducing rates to  $0.22\text{ mm a}^{-1}$  on the most exposed surf platforms). Subaerial downwearing was between  $0.45$  and  $0.97\text{ mm a}^{-1}$ . If these rates were characteristic of

the Pleistocene, then intertidal erosion would require 0.5–1.0 million years to plane a reef 1 km in width, well in excess of the time available in each glacial–interglacial cycle. Furthermore, shoreline retreat is an episodic rather than a continuous process in consolidated reef limestones, proceeding by alternating phases of intertidal notch cutting and then collapse. Next, intertidal backwearing is only part of the process of limestone removal, the other main process being solutional lowering of the exposed surface. On inland limestone substrates on Grand Cayman, mean subaerial erosion has been measured at  $0.37 \text{ mm a}^{-1}$ , with subsoil and submangrove rates of  $0.16 \text{ mm a}^{-1}$  and  $0.21 \text{ mm a}^{-1}$ , respectively. Thus if reefs were emergent by 125 m at the glacial maximum, then it would take over 300,000 years to remove such a column of limestone at the highest of these mean rates of lowering. Finally, the heterogeneity of lithification in reef limestones is reflected in the fact that erosion is extremely localized and gives rise to a pitted and cavernous microtopography rather than undifferentiated planation; thus, erosion is often accompanied by the preservation of original depositional reefal surfaces.

### Alternative explanations for the morphology of modern reef surfaces

It is clear from modern process studies that once reefs are formed they are difficult to remove by marine and subaerial erosion processes. In addition, the refining of the magnitudes and duration of ocean temperature change and sea-level fall following the late twentieth-century advances in environmental reconstruction do not provide the contexts within which wholesale reef removal can be realistically achieved. Given that present sea levels have been at or near to their present levels for at most the last 6,000 years and in some cases for only the last 1,000 years (only 0.6–0.1% of the last glacial–interglacial cycle), these conclusions suggest that the topography of modern reefs is often inherited from underlying, older reef surfaces (see also Chapter *Antecedent Platforms*). On the basis of bathymetric charts, Daly argued for the smoothness of these reef basements. Davis (1928) argued that such smoothness was the product of effective lagoon infilling during the upgrowth of marginal reefs. However, more recent detailed lagoon and shelf floor mapping, both of bottom morphology and, using seismic techniques, of bedrock surfaces below reefal sediments, has shown many basements to be characterized by highly irregular bedrock surfaces (Bloom, 1974), often organized into characteristic limestone erosional, or karstic, forms. Topographic features range in scale from small solutional features (e.g., solutional pipes in the Florida Keys; Dodd and Siemers, 1971) to marginal raised rims around saucer-shaped reef platforms (MacNeil, 1954; Harvey, 1977), “knoll and basin” topography in atoll lagoons (e.g., Chuuk lagoon, Federated States of Micronesia; Shepard, 1970), and “blue holes” in back-reef environments (e.g., Lighthouse Reef blue hole, Belize Barrier Reef; Stoddart, 1962), to large scale regional karst landscapes. The most comprehensive exposition of karstic control on

reef landscapes was provided by E. G. Purdy who, on the basis of seismic profiling and shallow drilling, argued that the regional morphology of the Belize Barrier Reef reflects a drowned doline karst in the drier northern barrier reef and on the central and southern barrier reef and a drowned tower karst in the lagoon and a flooded basement cockpit karst on the barrier reef margin itself. These latter two morphologies have resulted from the submergence of a karst marginal plain, supplied by solutionally aggressive drainage waters from the noncarbonate Maya Mountains. The underlying karstic control is clear on the Belize Barrier Reef because of the interaction of the depth below present sea level of the basement and the sea-level history at this location; Holocene reef development has been dominated by vertical, “catch-up” behavior and thus postglacial reef growth has exacerbated the underlying pre-Holocene topography (Purdy, 1974).

Elsewhere, the relations between basement depth, sea-level history, and postglacial reef growth modes (give-up vs. catch-up vs. keep-up) have been more complicated and given rise to a wider range of contemporary reef forms; in cases where the basement has been close to present sea level, reef growth may have completely filled the accommodation space and thus obscured any antecedent topography (Hopley, 1982). In some locations, the underlying antecedent topography is not a karst erosion surface but a depositional one and thus reef topography reflects colonization of stabilized carbonate shoal or reef top storm deposits (e.g., Garrett and Scoffin, 1977) or reef growth on underlying river levee (Choi and Ginsburg, 1982) or deltaic deposits (e.g., Maxwell, 1970).

### Conclusions

R. A. Daly’s “Glacial Control Hypothesis,” developed in the first quarter of the twentieth century, importantly engaged coral reef science with the question as to how reefs had reacted to Pleistocene changes of ocean temperature and sea level. Developments in Quaternary Science and in process geomorphology have, however, not supported Daly’s assumptions about the rapidity at which volcanic materials and coral reef limestones can be removed by erosion and thus the ease with which reefal surfaces can be planed to smooth lagoon floors and reefal shelves during the glacial phases of the Pleistocene. Rather modern reef topographies often reflect the complex underlying topography of much older, pre-Holocene surfaces and the erosional and depositional process histories to which they have been subjected. Antecedent topographic control is, however, variable and relates to the degree to which subsequent reef growth has either accentuated or obliterated the basement surfaces from which modern reefs have developed.

### Synonyms

Eustatic sea level; Glacial rebound; Postglacial sea level

### Definition

Glacio-hydro isostasy refers to the earth's response to changes in surface ice and water loading during glacial cycles. During the growth of an ice sheet, the crust is loaded in the areas of glaciation and the crust beneath and near the ice sheet subsides. During the decay phase of an ice sheet, the crust is unloaded and rebounds. This is the glacio-isostasy component. But as water is extracted from, or added into, the oceans during ice growth and decay, the oceanic crust also responds to the changing water load. This response is called the hydro isostasy. The two combined components, not uncoupled, are referred to as glacio-hydro isostasy.

### Introduction

The glacio-hydro isostatic effect is manifested in geological, geophysical, and geodetic observations. It is seen in the geological record as a complex spatial and temporal pattern of raised shorelines (Figure 1) in areas of former glaciation (primarily the glacio-isostatic signal) as well as along coastlines far from the former ice margins (primarily the hydro-isostatic signal). It is also seen in geodetic observations: as displacements of the crust, both vertical and horizontal; as sea-level change in tide gauge and satellite altimeter data; as changes in gravity measured by surface instrumentation and by satellite sensors and orbital perturbations; and as anomalies in the earth's rotation. It has implications for understanding sea-level change, paleogeographic reconstructions of coastal environments, archaeology, the stress state of the crust, and the computation of precise satellite orbits.

### Models for glacio-hydro isostasy

A zero-order description for isostatic response to loading is a model of local response of a crust–lithosphere that is unable to support shear stresses and that overlies a fluid mantle of zero viscosity. An ice load of  $H$  m thick and of density  $\rho_i$  would displace the crust beneath it by

$-H\rho_i/\rho_{\text{mantle}}$  or  $\sim 25\text{--}30\%$  of the thickness of the ice or water load. This model ignores the strength of the essentially elastic crust–lithosphere as well as the viscosity of the mantle, but it provides a useful order of magnitude estimate of the maximum displacement that may occur. Thus, beneath large ice sheets, the maximum crustal displacement may approach a kilometer and the seafloor within ocean basins may be displaced by 30–40 m for a globally averaged sea-level change of  $\sim 120$  m.

An improved model is one of regional isostasy in which the load is supported by an elastic crust–lithosphere layer that overlies a zero viscosity mantle. For loads of horizontal dimensions much greater than the lithospheric thickness, the displacement at the center is nearly equal to that predicted by the local model but at the edge of the load it is only about one half of this amount because the load is partly supported by the flexural strength of the lithosphere. Thus, along continental margins, the hydro-isostatic signal may reach 15–20 m for the above global sea-level change of  $\sim 120$  m. But this is still only an order of magnitude estimate and to fully describe the global pattern of sea-level change, more physically realistic models, that involve the mantle viscosity, are required.

Realistic models of the glacio-hydro-isostatic phenomenon include the following features:

- Physically realistic representation of the planet's response function, or rheology, to surface loading on timescales of thousands of years. The observational evidence indicates that the earth is still responding today to the unloading of the last great ice sheets such that the model requires elastic as well as viscous elements in the response function. For both mathematical expediency and because it provides a satisfactory explanation of the observational evidence, a linear viscoelastic response is usually assumed. Both depth and lateral variability in the rheology needs to be considered.
- A realistic description of the evolution of the ice sheets during the full glacial cycle. A detailed description of the individual ice sheets is required (on a  $0.5^\circ$  grid and preferably smaller) for the evaluation of the glacio-isostatic component, but for the hydro-isostatic component it is the total rate at which water is added or removed from the oceans that is the significant requirement.
- A detailed description of the ocean basin to ensure that meltwater from the ice sheets is properly distributed. This distribution has to satisfy the requirement that the ocean surface is an equipotential surface at all times and that the ice–water mass is conserved. Through time, the ocean basin deforms, the shorelines migrate and the ice sheets displace water on the shelves. The ocean basin deforms in response to both the ice and water loads and this introduces a coupling between the glacio- and hydro-components of the isostatic response.
- The ability to compute the deformation and the mass distribution of the earth–ocean–ice system through time and to relate this to the observational evidence for

**Glacio-Hydro Isostasy, Figure 1** Representative sea-level curves for different localities around the world. The time and sea-level scales are not the same for all examples. (After Lambeck and Chappell [2001]).

- sea-level change and shoreline migration, crustal deformation and gravity change, and the global inertia tensor.
- The feedback that occurs through the earth's rotation. As the inertia tensor is modified during the glacial cycle, the earth's rotation, centrifugal force, and the gravitational equipotential surfaces are also modified.
- High spatial resolution solutions are required. Sea-level changes above the threshold of observational

accuracies can occur, for example, over distances of 10 km or less across former ice margins or continental margins and the numerical solutions must be able to represent this.

The formulation of the glacio-hydro-isostatic rebound is well established but the definition of the rheological parameters or aspects of the ice models themselves are often less well known and are mostly inferred from the analysis of the rebound evidence. Thus, for descriptive purposes, the formulation serves as an interpolation device between fragmentary observational evidence that also allows for a degree of extrapolation beyond the limits of the time–space dimensions defined by the observational data.

### The sea-level response

In the context of coral reefs, the most important consequence of the glacio-hydro-isostatic response is sea-level change. Schematically, the equation describing sea-level change,  $\Delta\zeta_{\text{rsl}}(\varphi, t)$ , can be written as

$$\Delta\zeta_{\text{rsl}}(\varphi, t) = \Delta\zeta_{\text{esl}}(t) + \Delta\zeta_{\text{I}}(\varphi, t) + \Delta\zeta_{\text{T}}(\varphi, t) + \Delta\zeta_{\text{O}}(\varphi, t)$$

with

$$\Delta\zeta_{\text{I}}(\varphi, t) = \Delta\zeta_{\text{I-g}}(\varphi, t) + \Delta\zeta_{\text{I-h}}(\varphi, t)$$

$\Delta\zeta_{\text{rsl}}(\varphi, t)$  represents the change at location  $\varphi$  of the sea surface relative to land at time  $t$  compared to its present position at time  $t_{\text{p}}$ . The first term on the right-hand side represents the ice-volume equivalent sea-level contribution (ESL) and is a measure of the globally averaged sea-level change due to a change in ice volume. It is defined as

$$\Delta\zeta_{\text{esl}}(t) = -\frac{\rho_{\text{i}}}{\rho_{\text{o}}} \int_t \frac{1}{A_{\text{o}}(t)} \frac{dV_{\text{i}}}{dt} dt$$

$V_{\text{i}}$  is the ice volume at time  $t$  and includes the ice mass on continents and grounded on continental shelves.  $A_{\text{o}}(t)$  is the ocean surface area and is defined by the shoreline and the grounding lines of any ice on the shelves, both at time  $t$ .  $\rho_{\text{i}}$ ,  $\rho_{\text{o}}$  are the average densities of ice and ocean water. In the absence of any other factors that lead to changes in ocean volume, the ice-volume equivalent sea level is equal to eustatic sea level.

The second term,  $\Delta\zeta_{\text{I}}(\varphi, t)$ , is the combined isostatic contribution. It is schematically divided here into two contributions: the glacio-isostatic part  $\Delta\zeta_{\text{I-g}}(\varphi, t)$ , and the hydro-isostatic part  $\Delta\zeta_{\text{I-h}}(\varphi, t)$ . Both terms include contributions from the deformation of the crust under the time-dependent surface load and from the change in the gravitational potential of the earth–ice–water system (sometimes referred to as geoid changes). Coupling between the two isostatic terms arises from the deformation of the ocean basins and from the change in gravitational attraction by the ice. This is ignored in this

schematic description but not in the actual models (Lambeck et al., 2003; Mitrovica and Milne, 2003).

The third term,  $\Delta\zeta_{\text{T}}(\varphi, t)$ , allows for any tectonic contributions to sea level. Many reefs occur in areas of tectonic uplift or subsidence and the separation of these effects from the isostatic signals remains a major challenge. A frequently used criterion is to examine whether there is evidence for a fossil Last Interglacial reef at the same location. If this occurs within a few meters of present sea level, then the site can be considered to have long-term tectonic stability to better than 0.1 mm/year. Alternatively, if the sea-level behavior can be calibrated against sites of known tectonic stability, the comparison of model predictions and observations establishes rates of tectonic uplift or subsidence.

The fourth term,  $\Delta\zeta_{\text{O}}(\varphi, t)$ , includes any oceanographic or meteorological factors that cause sea level to depart from a long-term equipotential surface. These are generally treated as perturbations in high-resolution analyses of recent and Holocene sea-level change.

Despite most modern coral reefs occurring far from the ice margins of the last glaciation – far-field sites – both components of the isostatic response occur. The glacio-isostatic response here is characterized by a broad wavelength response, reflecting global-scale mantle flow driven by the growth and decay of the large ice sheets, and the sea-level response is not sensitive to the details of the ice sheets. More important here is the hydro-isostatic component and this is strongly dependent on the changes in the distribution of water around the site.

Figure 2 illustrates sea-level change at a continental margin site. At a time  $t$ , the land surface is at  $a - a'$  and the shoreline is at  $A(t)$ . Between  $t$  and the present,  $t_{\text{p}}$ , land uplift has occurred by an amount  $u_{\text{r}}$  and the new land surface is at  $b - b'$ . The ocean volume has also increased so as to raise the ocean level relative to the center of mass of the earth from  $\zeta_{\text{A}}$  to  $\zeta_{\text{B}}$  and the present shoreline is at  $B(t_{\text{p}})$ . The original shoreline will now occur at  $A'$ , at  $\Delta\zeta(t)$  below the present sea level. The relative sea-level change is therefore

$$\Delta\zeta(t) = (\zeta_{\text{A}} - \zeta_{\text{B}}) - u_{\text{r}}$$

and the change in elevation of any point (e.g., from  $C$  to  $C'$  on land or from  $D$  to  $D'$  offshore) measured with respect to the sea level of the epoch is

$$h(t) = h(t_{\text{p}}) - [(\zeta_{\text{A}} - \zeta_{\text{B}}) - u_{\text{r}}] = h(t_{\text{p}}) - \Delta\zeta(t)$$

This formulation is independent of the cause of land movement or ocean volume change but for the glacio-hydro-isostatic contribution only, the land movement component will depend on the response of the earth's surface to the changing ice–water load and the displacement of the ocean surface will depend on how any meltwater is distributed into the ocean basins and on the changing gravitational attraction of the solid earth and the ice on the water surface. In the case of glacio-hydro isostasy  $u_{\text{r}}$  and the radial displacement of the ocean surface ( $\zeta_{\text{A}} - \zeta_{\text{B}}$ ).

**Glacio-Hydro Isostasy, Figure 2** Schematic representation of relative sea-level change  $\Delta\zeta$  in an environment of land uplift  $u_r$  and a rise in the radial distance of the ocean surface ( $\zeta_A - \zeta_B$ ). (See text for details).

Consider the following simple model. At the end of a long glacial period,  $t_A$ , a volume of ice has been added rapidly into the ocean at a constant rate until a time  $t_B$ . The ocean volume then remains constant until the present  $t_P$  (Figure 3a). During the deglaciation the meltwater loads the ocean floor and induces flow in the mantle away from the areas of loading to beneath the continents and to compensate for the concomitant rebound beneath the ice sheets. The resulting subsidence of the seafloor will include an elastic response followed by a viscous response that continues after the load has stabilized and will still occur today. The ocean has to fill the void created by the subsiding seafloor and the sea surface, in a first approximation, follows the seafloor. In the middle of the ocean basins, the maximum subsidence can be roughly approximated by the local isostatic effect. At the continental margin, because the water loading occurs to one side only, the subsidence will be about 50% of that in mid-ocean, largely because of the flexural strength of the lithosphere. At far-offshore island sites, there is no change because the island subsides with the seafloor. Inland from the coast, within a deeply indented gulf, for example, where the crust is being progressively dragged down less by the ocean load, this change will approach  $u_r$  (Figure 3b).

The resulting spatial variability in the hydro-isostatic response will then have the following characteristics (Figure 3c):

- A small amplitude highstand near the coast with a maximum at the time meltwater addition ceased and with a magnitude that depends on the distance from the coast.
- A rise of sea level prior to the maximum highstand that occurs later with distance from the coast.

- Relative sea level at the LGM that varies across the shelf and that approaches the ice-volume equivalent value at some distance from the coast.

This scenario is an incomplete description of the relative sea-level change across the continental shelf since the glacio-isostatic contribution has been ignored, as has the change in gravitational potential during the deglaciation and subsequent relaxation phase and any change in water load caused by the migration of shorelines during the sea-level rise. Of these neglects the most important one is the glacio-isostatic factor, including the gravitational part. At the time of maximum glaciation a broad deformational bulge develops around the ice sheet and this slowly subsides during and after the deglaciation phase. When this bulge occurs in an ocean environment, additional space is created that draws water into it and away from the far-field locations where the glacio-isostatic signal becomes one of a falling sea level (Figure 3d). This contribution varies relatively slowly across the far field and the predominant spatial variability across a reef system will come from the hydro isostasy. The combined effect at the far-field sites is that a small amplitude highstand will also occur for many ocean island sites (Figure 3e). It is sometimes stated that ocean islands act as dipsticks and provide a direct measure of the changes in ocean volume. But this is a first approximation and in reality this occurs only at a few sites where the combination of all the factors contributing to the isostatic perturbation cancels out. These simple illustrations also point to a second common misconception, that it is the loading of the shelves that constitutes the hydro-isostatic correction. But this is one part of the water load only and the principal part comes from the long-wavelength load of the entire ocean floor.

**Glacio-Hydro Isostasy, Figure 3** Schematic components of the contributions to relative sea level at far-field sites across a continental margin. (a) The ice-volume equivalent sea-level (ESL) component. (b) The hydro-isostatic component at three locations across the margin. The inland site would correspond, for example, to the head of a deeply indented gulf. (c) The combined ESL and hydro-isostatic contributions. (d) The glacio-hydro-isostatic contribution at the far-field locations. This part varies only slowly across the area. (e) The total glacio-hydro-isostatic change in sea level.

### Some examples

Figure 4 illustrates predictions based on the complete theory, for sites equidistantly spaced across the Great Barrier Reef (Queensland, Australia) from within the inner Broad Sound, across the outer Reef and to Marion Reef in the Coral Sea. They are based on nominal ice and earth models that have been found to describe well the far-field behavior of sea level during Holocene time and are representative of a wide range of plausible models. In this model calculation, it has been assumed that all melting

ceased abruptly at 6,000 ( $C^{14}$ ) years BP and this results in the sharp highstand at this time. If this cessation was less abrupt then this peak becomes broader and its shape is diagnostic of changes in late Holocene ocean volumes. This example illustrates that with increasing distance from the continental coastline:

- the mid-Holocene highstand decreases in amplitude from a few meters maximum at the ‘inland’ sites;
- the oldest corals occurring at sea level become increasingly younger;

**Glacio-Hydro Isostasy, Figure 4** Predicted sea-level change for the complete glacio-hydro-isostatic rebound along a section at a spacing of ~35 km across the Great Barrier Reef (Australia) from the inner side of Broad Sound to Marion Reef within the Coral Sea. These results are for nominal earth parameters and ice sheets that cease all melting at 6,000  $^{14}\text{C}$  years before present.

- the pre-mid Holocene rise in sea level increasingly lags the globally averaged sea-level rise; and
- the Last Glacial Maximum sea levels increase in depth.

Across the Great Barrier Reef, adjacent islands and continental shoreline, the observational evidence generally confirms these trends although it has not always been interpreted in terms of the differential isostatic response. For example, the observation of a progressive decrease with distance from the shore of the oldest coral ages found at the upper limits of growth, has sometimes been interpreted as a result of outer reefs being less capable of keeping up with sea-level rise than inner reefs.

The amplitudes of the highstand and the lags in the response are dependent on the rheological parameters describing the earth's mantle and lithosphere so that the matching of observations and predictions enables these parameters to be estimated for the region of analysis. Glacio-hydro-isostatic studies of the formerly glaciated (near-field) regions likewise provide information on the earth's response function as well as on the dimensions and timing of the former ice sheets, particularly during their final decay phase. By an iterative process between far- and near-field regions, it becomes possible to separate the earth- and ice-model parameters that quantify the rebound formulation and thus to develop a predictive global model for that part of sea-level change associated with the glacial cycles. These models are best developed

**Glacio-Hydro Isostasy, Figure 5** Glacio-hydro-isostatic sea-level variation across the Japan Sea and adjacent areas at two epochs. (a) 20,000 (cal) years before present, at the time of the maximum glaciation. The contour interval is 5 m. (b) 7,000 (cal) years before present, at the time of the mid-Holocene highstand formation. The contour interval for sea-level change is 1 m. The red contours are negative and the orange contours are positive.

for the interval after the last glacial maximum but they have also been extended to earlier periods, particularly the Last Interglacial. In the context of coral reefs from this latter period, it is important to recognize that these isostatic processes also occur and that the elevations of Last Interglacial sea levels will exhibit similar patterns of spatial variability.

Figure 5 illustrates the predicted spatial variability for one region, the Japan Sea, that, in the absence of tectonics, is representative of most far-field regions. The results are for two epochs, the time of the last glacial maximum (LGM) and the time of the mid-Holocene highstand but the spatial variability is similar for all other epochs. Thus, even within relatively small regions sea level cannot be represented by a single curve. At the LGM the predicted sea levels vary by ~30 m, being significantly shallower in the Korea Strait, for example, than in the middle of the Japan Sea where it exceeds the ESL value. Likewise, the Holocene highstand amplitudes are predicted to occur up to 2 m above sea level in some locations but not in northern Hokkaido or the Kurile Islands.

## Conclusion

The phenomenon of glacio-hydro isostasy means that even in the absence of vertical tectonics, sea level at any time is spatially variable, that it can be rising in one location while falling elsewhere. This variability is a consequence of the earth's deformation under the changing load and to the changes in the gravity field. The mapping of this variability therefore provides information on both the earth's rheology and on the history of the ice sheets. But it also needs to be known if sea level is used as a reference for vertical tectonics or, for example, if reef response to changing sea level is to be investigated. The theory and implementation of the glacio-hydro-isostasy theory is sufficiently well developed for it to provide a sound basis for interpolating between the limited sea-level observations for the time since maximum glaciation and for reconstructing paleo shorelines and water depths.

## GLOBAL OCEAN CIRCULATION AND CORAL REEFS

John E. N. Veron

Coral Reef Research, QLD, Townsville, Australia

## Synonyms

Global scale currents

## Definition

Ocean circulation denotes ocean-scale current systems that change seasonally but persist from one year to the next.

## Introduction

Reefs develop in most parts of the world where reef-building (zooxanthellate) corals grow and where the ocean is warm. This geographic template is created by the world's great ocean currents (Figure 1). Currents therefore play a key role in the geographic extent of reef formation as well as in the dispersal of reef biota. They are also critical determinants of the pathways of species evolution.

The historical role of ocean circulations as drivers of reef and faunal distributions is closely linked to other drivers, not only temperature but also sea-levels and the configuration of the continents. Two very different scales – global and regional – operate simultaneously. Global scales over geological time provide the template of both coral reef distributions and zooxanthellate coral distribution. Regional scales over millennia or less control details of the distributions of corals and have a short-term, ecologically driven influence on reef development (see below).

## Origins of modern circulation patterns

At the start of the Cenozoic Era, ocean circulations were dominated by a circum-global equatorial path via the Tethys Sea and Central American Seaway. There was no circulation around Antarctica (the remnants of Gondwana) and all oceans were warm and sluggish, with no strong latitudinal temperature gradients as we have today. This pattern persisted until South America rifted free of Antarctica during the Late Eocene–Early Oligocene 40–35 million years ago (mya), and Drake Passage opened. At this point, for the first time since Gondwana formed, the Southern Ocean began circulating around Antarctica, moving eastward in response to the direction of rotation of the Earth and checked only by the coastlines of the three southern continents.

The formation of the Antarctic Circumpolar Current was the critical event that gave birth to modern circulation patterns. Where the three continents of South America, Africa, and (to a lesser extent) Australia project into its path, cold water is deflected north along the western margin of each continent. The currents then move westward in the tropics where they are warmed, and return south along

**Global Ocean Circulation and Coral Reefs, Figure 1** The global pattern of ocean circulation (after Veron, 2000).

the eastern side of each continent. These three anticlockwise circulations of the Southern Hemisphere oceans are in turn linked to clockwise circulations in the Northern Hemisphere in latitudinally zoned gyres (Figure 1). In effect, the opening of Drake Passage allowed the sluggish tropical circulations of the early Cenozoic to be replaced with stronger circulations, powered by the Antarctic Circumpolar Current, creating the latitudinal temperature gradients of today. It also formed an insulating blanket around Antarctica causing, at the time of formation, the surface temperature of the Southern Ocean to plunge by 10–15°C (Frakes et al., 1992).

During the latter half of the Cenozoic, there were two fundamental modifications to this pattern (Adams, 1981). The first was the widening of the North Atlantic, as, until this happened, the North Atlantic did not regulate global climates via the Ocean Conveyor and Gulf Stream as it now does. The second was the progressive reduction in size of the Tethys Sea. The Tethys, the evolutionary cradle of most tropical marine life, waxed and waned throughout the Early to Middle Cenozoic according to continental movements and sea-level changes, to be finally choked off during the Late Miocene (10 mya), a process which severed all tropical connection between the Atlantic and Indian Ocean (Figure 2).

There was one final event crucial to ocean circulation before Ice Age cycles took control: the formation of the Isthmus of Panama in place of the old Central American Seaway. This was a gradual process completed in

3.4 mya (Coates et al., 1992), which greatly enhanced the flow of the Ocean Conveyor to the North Atlantic (Burton et al., 1997) and allowed El Niño Southern Oscillation cycles to establish.

### Ocean circulation and biogeographic patterns

The distribution of corals and reefs during the Early Cenozoic essentially involved a transfer of biodiversity from the Old World of the Tethys Sea to the New World of the Caribbean and Central American Seaway. Through this process, coral diversity around the Central American Seaway reached a peak during the Oligocene and extensive reef development also spread throughout the central Indo-West Pacific, which had become clearly distinct from the Tethys.

By Early Miocene, the distribution of reefs was similar to that of today, with the major exception of the Tethys Sea which was held open only by a narrow passage between the Indian Ocean and proto-Mediterranean (Figure 2). The biogeographic patterns of corals at this time is unknown, but by then the Indo-West Pacific had inherited much of the diversity that had originally evolved in the Tethys and Caribbean (Veron, 1995). The Miocene ended 5.3 mya with the extinction of the last remnants of the ancient fauna of the Tethys. Late Miocene reef remains are very common in the western tropical Pacific (Kiessling and Flügel, 2002), with outcrops extending as far south as New Zealand (Hayward, 1977).

**Global Ocean Circulation and Coral Reefs, Figure 2** Positions of the continents during the Middle Miocene (around 15 mya). Extensive reef remains (in black) are scattered around the world and as far south as New Zealand (after Veron, 2008).

**Global Ocean Circulation and Coral Reefs, Figure 3** The role of poleward currents in latitudinal reef distribution along eastern Australia. The East Australian Current disperses coral larvae to the world's highest latitude atolls (Elizabeth and Middleton Reefs) and highest latitude reef (Lord Howe Island). South of the Great Barrier Reef, there are abundant corals but no reef development at the few shallow coastal localities – Flinders Reef (a sandstone outcrop) and the Solitary Islands – due to temperature and other environmental constraints (after Veron, 2000).

At this time, corals had yet to undergo one more major change in their global pattern of diversity. Throughout much of the Miocene (24–5.3 mya), but certainly by the Late Miocene, the eastern Atlantic had become too cold for reef corals as a result of the cold current plying along the west African coast (Esteban, 1980). The Atlantic thus became an isolating barrier separating the Caribbean from the Tethys where once it was a corridor.

### Ocean circulation and reef formation

It is only at oceanwide scales that there is only a clear correlation between the distribution of corals and the distribution of reefs, although surface currents play a dominant

role in both. The essential reason is that good reef development can occur in regions of low coral diversity: reef formation does not depend on a high coral diversity (Glynn et al., 1996).

With rare exceptions (carbonate platforms built by vermetid molluscs, serpulid worms, and non-scleractinian corals), the presence of zooxanthellate corals is essential for reef development. Thus, the oceanographic history of any major part of the world, as described above, determines the gross pattern of both reef development and zooxanthellate coral occurrence. Both require shallow substrata, minimal quantities of mud of terrestrial origin, high light levels, high salinity, a suitable temperature regime, and  $\Omega_{\text{aragonite}}$  of 3.8 or higher (see

**Global Ocean Circulation and Coral Reefs, Figure 4** The role of surface currents in dispersal of corals along the eastern Australian coast (a) and the islands of Japan (b). Dendrograms show similarity of species composition occurring at each site indicated. These include reef communities, non-reef communities, and outlying regions (after Veron, 1995).

Chapter “Corals – environmental controls on growth”). Of these constraints, all but temperature applies equally to corals and reefs on regional scales.

Temperature is more limiting for reefs than corals because of an ecological constraint: most corals can tolerate temperatures as low as 14°C for extended periods, but consolidated reefs will not accrete under 18°C because at that temperature corals cease to be competitive with macro-algae in most parts of the world (Veron and Minchin, 1992). Along subtropical continental coastlines where at least some zooxanthellate corals occur, reefs extend to a latitudinal limit defined by temperature which, in turn, is controlled by the strength of poleward currents (for example, Figure 3). In open oceans remote from continents, the same constraint applies where suitable substrates exist, but as poleward currents are weaker, the latitudinal extent of reef development is less.

One further aspect of the role of temperature in controlling the latitudinal range of reefs is that reefs can develop episodically, surviving as geological structures during intervals of emergence and cold (such as were created by the glacial cycles of the Pleistocene) and growing during interglacial warm intervals.

### Surface currents and dispersal

There is a wealth of information from experiments, genetics, taxonomy, and biogeography that coral larvae are able to make very long ocean journeys, some enduring weeks, even months, on the sea surface before settling (Richmond, 1987). Species endurance therefore depends on the speed and direction of currents as well as the existence of suitable substrates.

Survival during these voyages depends on time, therefore on the distance traveled, and speed.

Corals are dispersed along continental coastlines of eastern and western Australia by the East Australian Current and Leeuwin Current (respectively) in the Southern Hemisphere and along the islands of Japan in the north by the Kuroshio. In each case, there is an orderly

“drop-out” sequence where species numbers progressively attenuate (Veron, 1995). Each of these boundary currents varies in position and strength, each variation potentially causing changes in the number and variety of propagules reaching high-latitude reefs. Importantly, as each current flows poleward, propagules entrapped in them are on non-return journeys. As a result, these currents overwhelmingly dominate the nature and diversity of coral communities found today (Figures 3, 4a, b; Harriott and Banks, 2002).

Surface currents also play a part in defining the global center of coral diversity, the so-called “Coral Triangle” (see Chapter “*East Indies Triangle of Biodiversity*”; Figure 5).

There are multiple reasons why the Coral Triangle should be so diverse relative to other reef regions (Veron et al., 2009): (1) The Coral Triangle acts as a ‘catch-all’ for larvae moving *towards* the region, entrained in both the South Equatorial Current and the North Equatorial Current (Jokiel and Martinelli, 1992; Veron, 1995). (2) Dispersion occurs *away* from the Coral Triangle leaving that region biodiverse relative to other regions where attenuation has occurred. (3) Complex eddies created by the Indonesian Through-flow (Gordon and Fine, 1996) drive genetic mixing which constantly changes with wind, season, and (over geological time) sea level. Genetic mixing of this nature creates genetic heterogeneity through vicariance and reticulate evolution.

### Ocean circulation and evolution

Evolution in corals is exceedingly slow, whereas long-distance dispersal can be rapid – even within the time of a single generation. The two processes are therefore only tentatively linked, not only because of time but also because genetic pathways are constantly changed by variations in ocean currents.

The distance traveled by coral larvae and probably that of most other major invertebrate taxa can indeed be so vast that the majority of species found in, for example, the Great Barrier Reef also occur within the Coral Triangle

**Global Ocean Circulation and Coral Reefs, Figure 5** Contours of coral diversity (species richness). Species disperse from regions of high diversity, notably the Coral Triangle, to other Indo-Pacific regions. Many regions of the world, including most of the Atlantic (but not the Caribbean) and far eastern Pacific, have few, if any, corals and no reefs. However, over distances of a thousand kilometers, the occurrence of both corals and reefs is highly predictable (after Veron, 2008).

and a high proportion are even recognizable as far away as the Red Sea.

The relative strength and direction of the currents and the endurance of the larvae are key aspects of these spatial patterns – not just the patterns of today, but those of all times past, for as long as these species have existed. Today, most major currents are generally stable and move in predictable directions. However, over geological time, these same currents have changed their strengths and directions repeatedly. This has created changing geographic patterns of genetic mixing quite unlike genetic pathways normally found on land. The result, over geological time, is a template of constant change, which in turn is the mechanism that drives reticulate evolution (see Chapter *Scleractinia, Evolution and Taxonomy*).

The Kuroshio, the world's strongest continental boundary current, well illustrates change over time in both strength and direction. In historical time (decades to centuries), this current has repeatedly changed its path south of mainland Japan (Figure 6a), each time causing major redistributions of benthic fauna as well as local extinctions. Over geological intervals of 100,000s of years, combinations of glacial sea-level changes and tectonic uplifts have created enormous changes to the Japanese coastline and, consequently, the path of the Kuroshio (Figure 6b). Variations between these two extremes not only produced changes in distribution and diversity of most marine biota but also changes in their genetic compositions (Figure 6).

### Meso- and microscale circulation and environments

Most marine life undergoes dispersion, either long-distance (noted above) or within single reefs during larval stages in their life cycles, and most benthic and neritic life becomes established on particular areas of reef according to local environmental cues. At these mesoscales, currents are also the conveyors of food for filter – and detritus – feeding taxa, and oxygen and nutrients for all taxa. At yet finer scales, currents (generated by tides and waves) determine the growth form of branching corals and thereby the three-dimensional nature of most types of shallow reef habitats. These aspects of ocean currents are outside the scope of this article.

### Summary

The global distribution of reefs is a product of the major patterns of ocean circulation that have existed since Early Cenozoic which, in turn, were dependent on continental movements. Reef distributions are also controlled by the presence or absence of reef-building corals and therefore the physical parameters which control the growth of zooxanthellate corals. Of these, temperature is critical, the lower boundary of which is different for reefs and corals. Currents are also the pathways of dispersal of most marine taxa and are thus the principal drivers of evolutionary change. On finer scales, currents are an intimate part of reef ecological processes and morphologies.

**Global Ocean Circulation and Coral Reefs, Figure 6** Changing ocean circulation patterns of the Kuroshio. Over historical times (a), major changes have occurred in the path of the Kuroshio south of mainland Japan. Some of these are seen in fossil coral outcrops (arrowed). Over 100,000s years, the coastline has changed radically from sea-level changes and tectonic uplift, creating far greater changes to the Kuroshio (after Kimura, 1991). Variations between these extremes have created a constantly changing template for evolutionary change.

## GREAT BARRIER REEF COMMITTEE

---

David Hopley  
 James Cook University, Townsville, Queensland,  
 Australia

In 1922, the Queensland branch of the Royal Geographical Society of Australia set up the Great Barrier Reef Committee following an address to the Society by the Professor of Geology and Mineralogy at the University of Queensland, Henry Richards. The address, entitled “Problems of the Great Barrier Reef” highlighted the need for scientific investigation of the Reef and followed a visit by Richards to America to attend the Pan-Pacific Scientific Conference where, among others, he met W.M. Davis (Hill, 1985a, b; Jones, 1974; Bowen and Bowen, 2002).

Membership of the Committee was through invited nominations from the Government and Academic institutions in Australia and elsewhere. However, disagreements with the parent body, the Royal Geographical Society led to a separation of the Committee in 1924 although it incongruously maintained the title of Committee. Initial funding came from the Queensland Government and Universities of Sydney and Queensland and further valuable support came from the provision of places on survey vessels of the fledgling Australian Navy and the Commonwealth steamer that serviced the many lighthouses on the reefs and islands.

Early research was much influenced by Richards’ geological background with, for example, Sydney University graduates undertaking work into coastal landforms and sea level, published in the independent Transactions of the Great Barrier Reef Committee. However, Richards had larger targets in mind including investigations into the foundations of the Reef to see if Darwinian type subsidence was applicable. In 1926, a hole was drilled to 180 m on Michaelmas Cay, and in 1937 further drilling on Heron Island to 240 m was undertaken. Results were inconclusive as to the proving or otherwise of the nineteenth century hypotheses of Darwin, Dana, and others but did provide useful information, which was being quoted even 50 years later (e.g., Lloyd, 1973).

Another early aim of the Committee was to set up a research station on one of the reef islands but as this was not immediately possible, an alternative strategy was adopted and that was to promote an expedition based on a reef island for at least one full cycle of seasons. Discussions were held with various scientific bodies, especially in England and support came especially from the British Association for the Advancement of Science. The cay on Low Isles, north of Cairns, was the chosen site where 23 scientists were based under the leadership of (Sir) Maurice Yonge in 1928–1929. A variety of studies, including zoological, botanical, sedimentological etc., were undertaken and the large number of reports were published by the British Museum of Natural History. They have remained the basis for coral reef research ever since.

In addition to the main expedition, the Royal Geographical Society supported a smaller study of mainly islands of the southern half of the Great Barrier Reef (GBR). This was led by Professor J.A. Steers of Cambridge University and accompanied by Michael Spender and was followed by a second 4-month expedition mainly to previously unvisited islands of the Reef in 1936. Their results were published in the Geographical Journal and Reports of the Great Barrier Reef Committee (Steers, 1929, 1937, 1938; Spender, 1930). This work did much to highlight the value of reef islands as a source of geomorphological information on coral reefs and established Cambridge University’s Geography Department as a source of reef researchers.

Establishment of a permanent research station on the GBR was not possible until after World War II. Initially a relatively small facility, it was set up in 1951 on Heron

Island at the southern end of the GBR and close to the capital city of Brisbane. This has subsequently become one of the major reef research facilities in the world.

During the second half of the twentieth century, the Committee was very active in conservation issues of the GBR, something which Richards had originally seen as being important. Scientific evidence about the crown-of-thorns starfish and oil drilling on the Reef, and the need to create the Great Barrier Reef Marine Park Authority was presented to a number of government commissions.

The Committee also played a part in the organization of the Second International Coral Reef Symposium in 1973, which uniquely was held aboard the cruise ship "Marco Polo" travelling from Brisbane to Lizard Island and return. Also in the same year, the Committee was involved in the organization of a further expedition to the northern GBR. Enthusiastic support came from Sir Maurice Yonge and Professor Alfred Steers from the 1928–1929 expedition. Major input came from the Royal Society of London and from the Universities of Queensland (Queensland University and the new James Cook University of North Queensland). The leader of the expedition was Dr. David Stoddart of Cambridge University. Again, significant data was obtained especially from the reef islands and comparison with results from 1928–1929 to 1936 allowed some assessment of the dynamics of the islands. Results of this work were published in 1978 in the *Philosophical Transactions of the Royal Society*, London A, 291 and B, 184.

In 1988, after 66 years as an unattached committee with nominated membership, the Great Barrier Reef Committee became the Australian Coral Reef Society (ACRS) with subscription membership. However, continuity is recognized and this makes it the oldest organization concerned with coral reefs in the world.

## GREAT BARRIER REEF: ORIGIN, EVOLUTION, AND MODERN DEVELOPMENT

Peter J. Davies  
 University of Sydney, Sydney, Australia

## Introduction

The Great Barrier Reef (GBR) is arguably the largest coral reef system to have ever existed on the planet. It lies off the northeast Australian margin – a passive margin, but a margin which is being gradually consumed as a consequence of Australia's inexorable drift toward the New Guinea foreland basin and the trenches to the north. Unless plate motions change, the Great Barrier Reef is a temporary acquisition. The following is the story of its development to date – one of three major reef systems to have existed in the region since the Miocene, and the Great Barrier Reef owes its existence to both its predecessors.

## The architecture of offshore northeast Australia

The northeast Australian margin ([Figure 1a](#)) comprises the continental shelf and a number of marginal plateaux and rift troughs: the Eastern, Queensland, and Marion Plateaux; the Pandora and Bligh Troughs; the Osprey Embayment; and the Queensland and Townsville Troughs and the Cato Trough. In addition, a zone of narrow rift basins extend southeast beneath the shelf of the GBR from the Queensland Trough southeast toward the Capricorn Basin and separating the Marion Plateau from the inner and middle continental shelf. The entire margin is underlain by modified continental crust formed as a result of fragmentation of a northeastern extension of the Tasman Fold Belt (Gardner, 1970; Ewing et al., 1970; Falvey, 1972; Falvey and Taylor, 1974; Taylor, 1975; Mutter, 1977; Taylor and Falvey, 1977; Mutter and Karner, 1980; Symonds, 1983; Symonds Davies and Parisi, 1984). The main physical and structural elements of offshore Queensland are shown in [Figure 1b](#) and briefly described below:

## Eastern Fields Plateau

The Eastern Plateau is the most northern marginal plateau of the northeast Australian continental margin ([Figures 1a, b](#), and [2a](#)) and is bounded in the west by the Moresby, Pandora, and Bligh Troughs, in the south by the Osprey Embayment, in the north by the Moresby Canyon, and in

the east by the Coral Sea Basin (Figure 1a and b). The plateau has an average depth of 1,500 m, and covers an area of about 31,000 km<sup>2</sup> at the 2,000 m isobath. Eastern Fields Reef, the only modern reef on the Eastern Plateau, is about 45 km across at its widest point, and lies at the crest of the plateau near its northern margin. Submerged and buried reefs extend northeast from Eastern Fields Reef beneath the Moresby Trough (Davies et al., 1988). The northern and southern plateau margins are controlled by normal faults; the western margin is more complex, and appears to be a product of thrusting. The Eastern Plateau is founded on a complex of tilt blocks bounded by reactivated normal faults, some of which appear to have undergone both wrench and reverse movement (Davies et al., 1988). This deformation appears to have resulted from Late Oligocene and Miocene tectonism caused by the development of the New Guinea Orogen to the north (Pigram and Davies, 1987). This late phase of structuring is not represented on the other northeast Australian marginal plateaux.

### Queensland Plateau

The Queensland Plateau is the largest marginal plateau on the Australian continental margin and is one of the largest features of its type in the world (Figure 1a and b). It is bounded on the northeast by the Coral Sea Basin, on the west by the Queensland Trough, and on the south by the Townsville Trough. The plateau is roughly triangular in shape, and extends over an area of about 165,000 km<sup>2</sup>. Approximately half of the plateau surface lies above the 1,000 m isobath, with living reef systems at or near present sea level making up 10–15% of the surface. The largest modern reef complexes are Tregrosse and Lihou Reefs, lying along the southern margin of the plateau (Figure 1a). Both these complexes are nearly 100 km long from east to west, and 50 and 25 km wide, respectively, from north to south. The other major areas of modern reef growth are the Coringa, Willis, and Diana complexes, which are aligned north to south in the center of the plateau, and the large isolated pinnacles of Flinders, Holmes, Bougainville, and Osprey Reefs, which lie along the western margin of the plateau (Figure 1). In addition, drowned reefs have been reported from at least 25 different locations (Taylor, 1977; Mutter, 1977; Davies et al., 1988). Away from reef areas, the plateau surface is generally smooth and slopes northward. A distinct terrace at approximately 450–500 m depth connects both the Willis and Diana reef complexes and the Tregrosse-Lihou-Coringa reef complexes.

### Marion Plateau

The 77,000 km<sup>2</sup> area of the Marion Plateau lies directly east of the central Great Barrier Reef, and is bounded along its northern margin by the Townsville Trough and along its eastern margin by the Cato Trough (Figure 1a). The present plateau surface forms a deep water extension of the shelf of the central Great Barrier Reef, with water

depths ranging from 100 m along the western border to 500 m along the eastern margin. At present, reef growth is restricted to Marion Reef, on the northeastern corner, and Saumarez Reef, at the southeastern corner of the plateau (Figure 1a).

The Marion Plateau is bounded on three sides by rifts: the Cato Trough to the east, the Townsville Trough to the north, and in the west by a series of north–south-oriented, narrow half-grabens which separate the plateau from the Australian continent (Figure 1b). The most northern of these half-grabens appear to join the confluence of the Townsville and Queensland Troughs. In the early Tertiary, therefore, the Marion Plateau formed a separate marginal plateau. The basement beneath the Marion Plateau is a planated surface dipping gently northeast (Figure 2d and e). The only disruption to this surface occurs in the northeast corner where a basement high forms the pedestal on which Marion Reef developed. Basement beneath the plateau margins is steeply down-faulted into the troughs to the north and east and was completely transgressed during the Early Miocene, resulting in the development of an extensive carbonate platform on which four, progressively more, restricted reef growth phases occurred, the last of which is seen today on Marion and Saumarez reefs. Over most of the platform, shallow water carbonates ceased with late upper Miocene/Pliocene subsidence.

### The Swains Reef and Bunker Highs

The Swains Reef high (Figure 1a and b) is a structural high some 200 km long and 50 km wide to the southwest of the Marion Plateau and forming the eastern boundary of the Capricorn Rift basin (Figure 1b). It is probably a late Cretaceous feature when it formed the eastern side of the Maryborough basin, but became a prominent late Tertiary feature when rifting jumped from the Maryborough to the Capricorn basin and sea floor spreading unzipped northwest in the Cato Trough. Marine conditions were established over the Swains High probably in the late Oligocene/early Miocene. It is thought that reefs established in the Pleistocene. The Bunker High occurs to the southwest of the Capricorn Basin (Figure 1a and b). It formed an eastern volcanic source for the Cretaceous Maryborough Basin and following rifting in the Tasman Sea, the western edge of the Cainozoic Capricorn Basin. It was transgressed in the Miocene with shallow water marine calcarenites and foraminiferal limestones establishing as precursors to reefs in the Pleistocene of this southern region.

### The Great Barrier Reef

The Great Barrier Reef is a modern reef system which extends along the northeast Australian margin from 24.30 to 9.30°S (15° of latitude), a distance of 2,300 km from north of Fraser Island in the south to the Torres Shelf/Gulf of Papua in the north. There are estimated to be in excess of 3,600 individual reefs within this area.

Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 1 (Continued)

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 1** (a) The main physical features of the northeast Australian margin showing in particular the Great Barrier Reef, together with the other main plateaux and rifts. (b) The major structural features of northeast Australia. The location of major drill holes are shown (BB Borabi, P Pasca, AC Anchor cay, M Michaelmas cay, AQ Aquarius, CP Capricorn, W Wreck, H Heron, 209 DSDP 209, 811–824 ODP sites).

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 2** Schematic sections showing the generalized structure and sedimentary relationships on (a) the Eastern Fields Plateau, (b) north to south through the Queensland Plateau (c), west to east through the Queensland Plateau (d) east to west through the Marion Plateau and (e) north to south through the Marion Plateau.

The shelf occupied by the Great Barrier Reef is narrowest in the north along 14°S (23 km) and widest in the south along 21°S (260 km) (Figure 3). Reefs occupy the whole shelf in the northern region, but apart from fringing reefs along coasts and large islands, reefs occur largely in the mid- to outer shelf in the center and south. The bathymetry is complex and varies regionally, but six distinct bathymetric regions can be defined (Figures 1 and 3). Area A (Figure 3) in the extreme north (9–12°S) is a narrow rimmed high-energy platform characterized by a shallow narrow shelf (50–75 km wide) and a steep continental slope. Reefs occur in four clearly delineated groups: the reefs of the western Torres Shelf, the Warrior

line continuing northward off the end of Cape York, the mid-shelf plethora of small patches, and the outer shelf barrier reefs. In the region 12° and 16°S the shelf is no more than 50 km wide except east of Cape Flattery where it achieves 75 km. Water depths are generally shallow, the outer shelf being the only place where water depths greater than 50 m occur. The most prominent reef features in the region are the outer shelf line of barrier or ribbon reefs forming an almost continuous shelf edge between Capes Grenville and Flattery but still prominent down to about latitude 17°S and east of which the continental slope is precipitous to a depth of 200–300 m, and also the gigantic mid-shelf platform reefs, particularly, northeast of

Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 3 Physiographic variation in the Great Barrier Reef province.

Princess Charlotte Bay. Area B (Figure 3) occurs between Cape Bedford and Hinchinbrook Island (16° and 18°S), where the shelf varies in width from 50 to 75 km, and is bathymetrically relatively simple. Reefs generally occur as fringing reefs along the coast and as large platform and ribbon reefs on the mid- to outer shelf; these are separated from the coast by a channel or inner lagoon with water depths of around 35 m. The outer shelf ribbon reefs form a discontinuous barrier particularly in the northern part of the area but becomes gradually more discontinuous to the south, ceasing to exist as a line of reefs to the south of Cairns, at latitude 18S but continuing as line shoals on the shelf edge averaging 60 m water depth. Area C (Figure 3) occurs between Hinchinbrook Island and the Whitsunday Islands (18° and 20°S) where the shelf takes a clear change in direction, changing from north–south to north–west to south–east. The width of the shelf also widens considerably to an average of 90–125 km. The inner 50–80 km of the shelf is reefless except for fringing reefs attached to high islands but eastward, the mid- to outer shelf slopes gently from 45 to 75 m, at which depth a marked change in slope occurs, reflecting the inner edge of an outer shelf terrace some 20–30 km in width. The Slashers, John Brewer, Myrmidon, Pith, Wheeler, Keeper, Bowl, Stanley, and Viper reefs occupy this outer shelf terrace. A drowned barrier reef complex occupies the outer shelf of the 75 m terrace and extends to the south-east for 200 km. Area D (Figure 3) occurs between the Whitsunday Islands to the Swain Reefs (20° to 22°S), the shelf continuing its northwest to southeast orientation away from the coast giving rise to a dramatic increase in the width of the shelf to over 300 km in the south. The inner two thirds of the shelf are reefless except for small fringing reefs around continental islands; eastward, however, the outer shelf is a plethora of gigantic reefs forming the Pompey complex and smaller more dispersed reefs forming the Swains complex. Area E (Figure 3) occurs to the south of the Capricorn Channel (22° and 24°S) where the shelf is less than 100 km wide, with the Capricorn and Bunker reefs occupying only a narrow zone on the mid-shelf. Well-known reefs in the region include Heron, Wreck, One Tree, Fitzroy, Fairfax, and Lady Musgrave.

Small drowned reefs occupy the shelf edge in 80–100 m of water (Davies et al., 2004). In addition to the reef ecosystem, *Halimeda* bioherms and biostromes comprise an almost equally important ecosystem in the northern and central, southern Great Barrier Reef (See *Halimeda Bioherms*, this volume).

### The rift basins

In addition to the platforms, the architecture of the north-east Australian margin is dominated by a series of rift basins (Figure 1a and b) which formed as a result of fragmentation of a northeastern extension of the Tasman fold belt (Gardner, 1979; Ewing et al., 1970; Falvey, 1972; Falvey and Taylor, 1974; Taylor, 1975; Mutter, 1977;

Taylor and Falvey, 1977; Mutter and Karner, 1980). The Pandora and Bligh Troughs and the Osprey Embayment occur in the north; the Queensland and Townsville Troughs in the central region and the Cato trough occupies the eastern and southern sections of the GBR. Relatively, smaller rift basins are also known to underlie the shelf of the Great Barrier Reef – the Papuan platform, the Halifax basin, the Whitsunday basin, and the Capricorn basin (Figure 1a and b). In the north the Papuan platform is a thick (? 4–5 km) Jurassic to Recent basin containing reefs within a fluvio-deltaic sequence representing the vast outpourings from the Fly River in New Guinea. The poorly defined Halifax Basin is a major structure beneath the continental shelf to the east of Townsville and underlies the central outer GBR: it is a Cretaceous/Tertiary basin covering some 60,000 km<sup>2</sup> and a maximum thickness in excess of 4,000 m. It lies at the intersection of the Queensland and Townsville Troughs. The Whitsunday Basin is a very shallow structure containing little more than 1,000–1,500 m of Cretaceous/Tertiary sediments underlying the region to the west of the Pompey and Swains reefs and may represent a connection between the Halifax and Capricorn basins. In the south, the Capricorn basin is sandwiched between the Bunker and Swains Highs.

### Bunker and Swains Highs

The Queensland and Townsville Troughs lie adjacent to the central/ northern reef region. Directly adjacent to the Great Barrier Reef (Figures 1a, b and 4a, b), the Queensland Trough occupies the region between the continental shelf and the Queensland Plateau between 14°S and 17°30'S. The floor of the trough slopes northward from 1,000 m at the junction with the Townsville Trough to around 3,000 m at its junction with the Osprey Embayment. Rather than being a simple graben, the Queensland trough may have been initiated in an oblique wrench zone caused by left-lateral movements between Australia and the Queensland Plateau (Symonds et al., 1984). The Townsville Trough is a west to east trough separating the Queensland and Marion Plateaux. It is over 500 km in length and 150 km wide. At its confluence with the Queensland Trough, the Townsville Trough is 1,000 m deep, deepening eastward to 3,000 m at its exit into the Coral Sea Basin. At this eastern end, at about Longitude 154°E, a bifurcation sends one branch south into the Cato Trough and the other winding sinuously north into the Coral Sea Basin. The Capricorn Basin started in the late Cretaceous as the result of an eastward shift of the Maryborough basin rift axis to the east concomitant with spreading in the Cato Trough. The basin extends in a northwest to southeast direction and is 500 km long by 250 km wide and is bordered by the Bunker and Swains Highs. This early to late Cretaceous rift phase development preceded continental breakup and the formation of the Coral Sea Basin by sea floor spreading in the Paleocene (62–56 million year BP) or latest Cretaceous (Weissel and Watts, 1979; Symonds et al., 1984).

Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 4 (Continued)

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 4** (a) Cross section of the Queensland trough and the stratigraphy of ODP drill holes across the trough; (b) Cross section of the Townsville trough and stratigraphy of ODP drill holes across the trough.

A major outcome was the development of a series of interconnected three-branch rift systems with the Townsville and Queensland Troughs and the Osprey Embayment representing failed arms of such a system (Mutter and Karner, 1980). These troughs are the most important structural elements associated with the formation of the Great Barrier Reef Province.

### Causes of architecture

The causes of the architecture described above are rifting, drifting, subsidence, sea-level/climate change, and collision. These are briefly summarized as follows:

#### Rifting

Late Cretaceous extension formed the basins described above, all of which are rift basins proximal to carbonate platforms. Of particular importance is the Queensland-Townsville-Cato rift systems, but also of importance if less developed is the rift system extending south from the Queensland trough through the Whitsunday basin to the Capricorn basin separating the Queensland shelf from the Marion and Queensland plateaux. The rifting process has clearly influenced the form of platform development in both, a general way through influencing the shape of the platforms and providing a substrate for shallow water deposition, but also in a specific way through the influence of fault blocks as sites for early reef development (Figures 2 and 5a, b).

#### Subsidence

The effect of subsidence is mainly to produce space. It can also have the effect of termination. Quantitative subsidence data for northeast Australia in four wells, Anchor Cay 1, DSDP Site 209, Capricorn 1A, and Aquarius 1 are shown in Figure 6. This data indicates that northeast Australia has not subsided solely as a result of uniform post-rift thermal cooling; rapid subsidence pulses have occurred at different times, and such pulses have clearly initiated transgressions. In the northern region at Anchor Cay, subsidence increased to 50 m/million years in the Miocene and increased again to 149 m/million years in the Pliocene. On the Queensland Plateau, at ODP site 209 subsidences doubled after the middle Miocene. In the Capricorn Basin, major subsidence of 75 m/million years occurred in the middle Oligocene and again in the Pliocene with uplift in the intervening early Pliocene. In the north and south, subsidence pulses occurred in the Miocene and the Pliocene. Seismic data from the central to northern shelf (Townsville to north of Cairns) shows a mid-shelf hinge of subsidence, delineating the point from which sediment packages thicken eastward. The northern shelf north of Cairns lies dominantly west of this hinge line; in the central region, most reef development occurs adjacent to the hinge line whereas southwards the Pompey and Swain reefs occur well to the east of the hinge line. There is fundamental control of reef growth by basement subsidence.

#### Drift

Hotspot (Duncan, 1981; Wellman, 1983) and magnetotratigraphic studies (Idnurm, 1985, 1986) define the basis for reconstruction of Indian-Australian plate motion through the Cenozoic (Figure 7a). Since the late Eocene when northeast Australia was located between 29° and 44°S, the continent has moved almost directly northward to its present position between 9° and 24°S. This movement would have resulted in profound climatic changes along the northeast Australian margin. Simplistically (Figure 7), the northern tip of northeast Australia would have entered the tropics only 25 Ma ago whilst the southern part of the Great Barrier Reef would have entered the tropics only in the last 1 Ma with substantial impact on the likely sedimentary facies that could have formed. However, a more detailed analysis of the effects of plate motions on paleo-oceanography (see Davies et al., 1989, p. 65) gives a much more precise analysis (Figure 7b) from which the following conclusions are drawn:

1. In the earliest Eocene, temperatures were very briefly warm enough for coral reef growth. Chaproniere (1984) reported large foraminifera from a dredge haul off the northwest Queensland Plateau, which he concluded grew in waters with temperatures of 18–27°C.
2. Sea surface temperatures from the middle Eocene to the middle Early Miocene (44–19 Ma) over the whole northeast Australian margin were temperate.
3. During the early Miocene sea surface temperatures off northeast Australia were marginal for coral reef development. In modern parlance, they were subtropical, comparable to southern Queensland today.
4. A rapid rise in sea surface temperatures occurred in the early mid-Miocene. Conditions were warm enough for coral reef growth in the northern and central GBR.
5. During the upper Miocene, tropical conditions persisted in the north and center but warming slowed in the south and conditions were not conducive for coral reef growth. Subtropical conditions prevailed in the south.
6. During the Pliocene and Pleistocene, the entire northeast Australian margin was situated within the tropics.

The consequences of these apparently simple conclusions are substantial and fundamental for northeast Australia:

- a. Any tropical platform must be underlain by a temperate platform and that initial rifting of the margin will contain temperate facies sediments.
- b. The consequence of the drifting model of sediment development is that reefs grew first in the north and, progressively, later in the south depending on SST.
- c. Tropical facies development will thin southward and overlie a progressively southerly thickening subtropical to temperate section. Facies diachroneity is, therefore, a fundamental factor of a stratigraphy dominated by plate motion through climatic belts.

The conclusions can be tested by comparing present day facies distributions along the east Australian margin with

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 5** Seismic sections across (a) Borabi, Pasca, Eastern Fields Plateau and Pandora Trough and (b) northern margin of the Marion Plateau showing the plateau edge reefs. Both sections show the importance of faulted margins as the sites for large reef systems. (c) western parts of the Queensland Plateau.

### Great Barrier Reef: Origin, Evolution, and Modern

**Development, Figure 7** (a) Projected latitudinal movement of northeast Australia throughout the Cenozoic. The northern boundary corresponds to Anchor Cay (presently 9°30'S) and the southern boundary to Heron Island (presently 24°S). (b) Surface water temperature envelope for the northeast Australian region throughout the Cenozoic, showing periods when temperatures were suitable for reef growth. The Miocene "phosphate" spike which inhibited reef growth is also shown (see Riggs, 1984).

the vertical facies seen in drill core from the Gulf of Papua. The present day sediment distribution on the outer continental shelf shows three major facies (Marshall and Davies, 1978):

North of Latitude 24S-tropical carbonate and clastic sediments dominated by corals and *Halimeda*.

Latitude 24–28S – subtropical coralline algal coated grains (rhodoliths), encrusting foraminifera, bryozoa.

South of latitude 28S – branching bryozoan/foram/molluscan facies.

A similar facies sequence occurs vertically in the Borabi No. 1 drill hole in the Gulf of Papua (Figure 8a). The bottom to top facies variations mirror those on the present shelf from south to north, and including the change to foreland basin clastics in the Gulf of Papua. The effects of drift, therefore, are as shown in Figure 9.

### Sea-level variations

Operating relatively in conjunction with subsidence, the effects of sea-level variations on platform development on the northeast Australian margin are different on the continental shelf and the marginal plateaux. On the shelf, high sea levels are carbonate-dominated and low sea levels are terrigenous-dominated on shelf and slope, and unconformities are widespread. However, on the oceanic plateaux where no terrigenous source occurs, high stands are reef or periplatform dominated and lowstands are dominated by unconformity development and caliche formation on the platform and carbonate gravity deposition and peri-platform deposition on the steep slopes.

### Collision

If, as a result of plate motion, a passive margin moves into a compressional tectonic regime, the carbonate platforms developed on that margin will be profoundly affected. They will become embroiled in mountain building and possibly subduction. These effects are seen on the northern edge of the Australian craton, which collided with an island arc complex in the Oligocene. The sequential development of the platform during collision is shown in Figure 10. This convergent history, leading to foreland basin development and mountain building, paradoxically, first led to an expansion of the area of carbonate deposition, but was followed by contraction, demise, and burial of the carbonates by clastic detritus (Pigram and Davies, 1987; Davies et al., 1989). This may be the fate of the whole of the GBR if Australia's northern motion is not arrested.

### Establishment of reefs in northeast Australia

As a consequence of the processes and architecture described above, coral reefs have been established on three occasions (1) in the early to late mid-Miocene (2) in the uppermost Miocene, and (3) in the Pleistocene.

Reefs first established on the Papuan shelf at Borabi and Pasca. Seismic (Figure 5) and drill hole data (Figure 8) show early to mid-Miocene reefs at Borabi established on pre-reefal red algal banks and also on a basement high at Pasca. On the Queensland Plateau (Figures 4 and 5b) reefs established in the Middle Miocene, once again on red algal banks (Brachert et al., 1993). On the Marion Plateau (Pigram et al., 1992) an extensive reef system covered over 400 km of the plateau and was established and reestablished on the plateau and along its northern edge (Figures 4 and 5). These reef systems terminated at different times and for different reasons.

Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 8 Details of drill holes on the northeast Australian margin.

23/OQ/116

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 9** Aspects of the structural history and sedimentologic framework of northeast Australia illustrated by schematic sections across the north, central and southern regions. An interpretative north to south tie shows the thinning and thickening of tropical and temperate sediments as a consequence of drift.

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 10** Cenozoic palaeo-oceanography of the Gulf of Papua/northern Great Barrier Reef showing the effects of progressive foreland basin development on carbonate platforms during (a) Eocene, (b) Early Miocene, (c) Late Miocene and (d) Pliocene. The schematic sections are orientated approximately northeast-southwest. Approximate palaeolatitudes are shown for each section.

In the north, reef growth at Borabi and Pasca through development of the foreland basin, and the southward flooding of fluvio-clastics caused the eventual migration of reefs eastward. On the Queensland Plateau, reefs terminated at 13.7 Ma due to subsidence of the plateau. On the Marion Plateau, reef growth terminated at 10.7 Ma as a consequence of a major fall in sea level in excess of a 150 m (Pigram et al., 1992).

Reefs reestablished in the north on Anchor Cay and Pandora in the upper Miocene and Pliocene, but not on the Queensland and Marion Plateaux for two reasons. First, an upper Miocene (7 Ma) subsidence pulse affected both plateaux (Figure 4) and secondly, oceanographic cooling established over the region at 6 Ma (Isern et al., 1993) inhibiting reef establishment, probably related to the Messinian glacio-eustatic sea-level fall. Reefs never

again established on the Marion plateau except at two places, Marion reef on the extreme northeastern edge and Suarez reef in the extreme southeast. This likely occurred in the Pliocene as it did on the Queensland Plateau (Figure 5c). This phase of growth substantially contracted on the Queensland Plateau by a third phase of subsidence at 3.7 Ma, drowning much of the plateau and in the north probably initiating further eastern migration of the reefs at Pandora. This pulse probably also established the main shape of the Australian continental shelf. However, the third phase of reef growth – the Great

Barrier Reef – did not establish at this time; it occurred much later.

### Establishment of the Great Barrier Reef

The Great Barrier Reef, as we know it, started in the late Pleistocene, much later than had been previously thought, and very much later than when the main architecture of the shelf had been established. The evidence for this is in the drill holes from Ribbon 5 and ODP 820 (Figure 11a). These data are summarized as follows

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 11** Stratigraphy defined for (a) Ribbon Reef 5. Ribbon 5 data also shows the reef front morphology and its correlation with ODP 820 (b) Boulder Reef, and (c) ODP Site 820.

### Ribbon Reef No. 5

Drilled in 1995, the detailed description of the corals, sediments (Webster and Davies, 2003) and coralline algae (Braga and Aguirre, 1997) in a core from Ribbon Reef 5 define the basis for understanding the establishment of the Great Barrier Reef. The litho-logs (Figure 11a) divide into three parts:

**0–96 m** – Six reef horizons comprised of two coral assemblages (1) robust branching *Acropora* (*humilis*, *robusta*, *palifera*, *Stylophora* (*pistillata*) and *Pocillopora* (*verrucosa*, *damicornis*) with associated massive *Goniastrea* and *Platygyra* and (2) Massive *Porites* (*lutea*, *solida*) with associated encrusting *Porites* and *Montipora*. Boundaries between reef horizons are identified by combinations of prominent horizons of pale brown sediment containing areas of calcitized plant cells, radiometric dating, negative shifts in  $\delta^{18}O$  values, exposure horizons, color changes from pink to brown, changes in algal associations and shifts in sediment facies (Webster and Davies, 2003). Algal associations throughout reflect shallow water tropical environments.

**96–158 m** – A rhodolith sequence dominated by four rhodolith grainstone horizons, coralline algal grainstones/packstones and two in situ coral framework horizons. The two in situ coral framework horizons represent the oldest reef horizons encountered in the Ribbon 5 core and separate the rhodolith horizon as into an upper and lower section. Changes from coral to rhodolith-dominated horizons are reflected in changes in the coralline algal associations and in one instance at 130 m by a sharp irregular surface and a substantial shift in the  $\delta^{18}O$  record. The algal associations define lower and upper subtropical environments with tropical reef horizons sandwiched between, i.e., the earliest reef growth occurred on a substrate of subtropical rhodolith grainstones.

**158–210 m** – 52 m of alternating grainstones/packstones and packstones/wachestones. The former are comprised of poorly sorted (rudaceous (4 mm) to medium sand) fragmentary corals, encrusting and branching corallines, bryozoans, foraminifers (*Amphistegina*, *Ilerostegina*, encrusting forams), molluscs, serpulids, echinoids, and gastropods: fresh water diagenesis throughout is indicated by interparticle spaces infilled by thick calcite rims, druses, and syntaxial overgrowths while mouldic porosity is developed within molluscs, corals, and especially *Halimeda*. The latter are well sorted, sometimes graded but finer grained (medium to coarse sand) with similar clasts but with up to 50% lime mud dispersed unevenly; little fresh water diagenesis evident. Boundaries between the grainstones/packstones and packstones/wachestones are sharp. Corals are subordinate to coralline algae, of which there are two assemblages, a shallower water *Lithophyllum* assemblage and a deeper water *Mesophyllum* assemblage; both occur today on the warm temperate to subtropical mid- to outer shelf of southern Queensland, south of the Great Barrier Reef (Braga and Aguirre, 1997). The sediments are typical of the same region. The wachestones/

packstones are defined as outer shelf (+60 m water depth) highstand deposits while the grainstones are defined as mid- to inner shelf regressive or lowstand deposits. The relatively sharp boundary between the facies types is, therefore, “event driven” by oscillating sea levels. The fresh water diagenesis is due to exposure in the lowstand effecting the grainstones but not the highstand wachestones/packstones. They are unlikely to represent the debris flows and turbidites postulated by Braithwaite et al. (2004).

### Ocean drilling program site 820

Drilled in 1991, Site 820 forms part of a suite of holes (819, 820, and 821) drilled immediately in front of the Great Barrier Reef in Grafton Passage, east of Cairns (Davies et al., 1991). While Site 821 is considered the most complete sedimentological section, it unfortunately suffers from intense fresh water diagenesis and Site 819 has a major hiatus in the upper part of the section. Site 820 is, therefore, considered to be by far the most complete section and the basis for the interpretations shown in Figure 11c (Davies and Peerdeman, 1998). Three sedimentologic units are recognized:

Unit A 0–65 m composed of wachestones separated by 8 m thick sandy bioclastic packstones composed of planktonic and benthic forams, mollusks, pteropods, minor echinoids, corals, corallines, bryozoans, rhodoliths and *Halimeda*. High and low sedimentation rates reflect alternating high and low sea-level oscillations. Seismic imaging shows aggradation with clear erosional geometries reflecting similar sea-level oscillations.

Unit B 65–145 m composed of wachestones and thin packstone units overlying wachestones and thick packstone units. A major reduction in sedimentation rates coincides with the boundary between Units A+B while alternating high and low rates in Unit B are thought to reflect oscillating sea levels. Seismic imaging shows the upper wachestones and thin packstones to be aggrading packages and the lower wachestones and thick packstones as prograding packages, the boundary occurring at around 110 m in the core.

Unit C – between 145 and 220 m dominated by sandy packstone beds and minor wachestones. An unconformity may occur in this sequence while seismic imaging defines prograding sediment geometries.

In all of the above, there are good agreements between stratigraphic, sedimentologic, and seismic data. However, it is when this data is tied to the isotope data (Figure 11c) that it starts to make sense in terms of the origin of the Great Barrier Reef. Three principal isotopic sequences are recognized:

- (1) Between 0 and 75 m (Unit A above) the signal is dominated by low frequency, high amplitude variation defined by Peerdeman et al. (1993) as related to the orbital eccentricity frequency. This isotopic sequence extends from isotope stage 1–8 and, therefore, has

a base at around 300,000 years. Kroon and Alexander (1993) interpret this signal to indicate a progressive decoupling of surface and bottom water temperatures and raised surface water temperatures.

- (2) Between 75 and 145 m (Unit B above), the signal is characterized by a much higher frequency as well as high amplitude. Peerdeman et al. (1993) interpret this as dominated by the obliquity signal and extending from isotope stage 9–19 at the Brunhes/Matuyama boundary. Davies and Peerdeman (1998) divided the section into two parts (2–1) between 75 and 110 m (isotope stages 9–13) characterized by low frequency high amplitude and (2–2) between 110 and 143 m (isotope stages 13–19) characterized by a much higher frequency and also a high-amplitude signal. These correspond with the division in packstones thicknesses noted above.
- (3) Between 145 and 220 m (Unit C above), the signal is characterized again by a much lower frequency (perhaps dominated by the eccentricity signal) and has high amplitude and as such is similar to the section above 75 m.

Peerdeman et al. (1993) consider the boundary at 75 m as a critical event in the history of the margin. Using the difference between the planktonic O18 signal in the Site 820 core and the benthic O18 signal at the deep sea Site 677 (Shackleton and Hall, 1989), they defined sea surface temperature variation for the northeast Australian margin which showed a substantial rise in temperature of around 3–5°C at around 75 m in the core (around isotope stage 9). This temperature variation corresponds to a change in frequency and amplitude of the isotope signal arising from the change from obliquity to precessional orbital cyclicity. Kroon and Alexander (1993) recognized a similar temperature change at Site 819. Further, Jansen et al. (1986) also recognized a fundamental change in isotope frequency at the 9–8 boundary as defining a change from lower to higher sea surface temperatures leading to the establishment of more interglacial conditions in the period of isotope stages 1–8. At sites 820 and 819, the boundary at 65 m is, therefore, a globally driven change dated at around 300,000 years. Further, the changes defined at the B1/B2 boundary, particularly the change from prograding to aggrading geometries (dated as just prior to 465 ka) reflects a change from shallow to deeper water, coincident with major regional oceanographic reorganization in the Southern Ocean (Kuijpers, 1989; Nelson et al., 1988). The boundary may also mark the change from an obliquity signal to the eccentricity signal seen in Unit A, with Unit B1 representing the transitional warming.

### Relations between Ribbon 5 core and ODP site 820 and implications

The proposed relations and reconciliation of the two data sets are shown in Figure 11a. The profile to the east of Ribbon 5 is one proven by profiling and submersible examination (Phipps et al., 1985). The fundamental change

from subtropical rhodoliths to tropical reef reflects a temperature change and just such a change is seen in the isotopic signal at Sites 820 at a depth of 65 m. The reef section is thus equivalent to Unit A (isotope stages 1–8) and the rhodolith section is equivalent to Unit B1 (isotope stages 9–13). Initial reef establishment of the coral frameworks in the middle of the rhodolith section must, therefore, date at sometime after 465 ka while the firm establishment of the main reef section above 96 m dates from around 300,000 years. The six stacked reefs at Ribbon 5 correspond to sea-level highstand growth phases, the first being either stages 8 or 9. The rhodolith section, equivalent to B1, represents the transitional warming suggested by the change in the obliquity signal noted above. This would be equivalent to conditions operating today to the south of the Great Barrier Reef on the south Queensland shelf (Davies et al., 1991). Further the sea-level oscillations defined by the wachestone/packstone alternations at Site 820 and representing warming and cooling episodes, serve also to explain the reef intercalations within the rhodolith sections. Davies and Peerdeman (1998) propose that the facies variations on that shelf and their lateral migration during oscillating sea level, define a model for the sub-reef rhodolith section at Ribbon 5 and explain the reef frameworks within that section.

### Cross-shelf growth of the great barrier reef

Once established in the shelf edge zone, is it right to assume that reefs quickly spread everywhere on the shelf? The results of a second borehole at Boulder Reef (Figure 11b) on the inner shelf and drilled during the Ribbon 5 campaign suggest otherwise. Four stacked reef sections (R1–R4 in Figure 11b) sit on siliciclastic mud and clay foundations at a depth of 34 m. The siliciclastics extend to 86 m where drilling terminated; however, coral-bearing units (R6 and R5) lacking a true framework occur within this mud section and have been interpreted as low-diversity coral communities reworked to form a rubble (Webster and Davies, 2003). Their presence is, however, significant. The base of the core has been tentatively dated by ESR as  $210 \pm 40$  ka, which suggests that the beginning of reef growth on the inner shelf was much later than on the outer shelf. Two failed attempts (R5 + R6, Figure 11b) were followed by the establishment (R4) of a reef structure, after which Boulder Reef was reestablished on three later occasions. The two failed attempts at 55 m (R5) and 63 m (R6) and the beginning of the main reef section (R4 at 34 m) occurred on siliciclastic foundations, testifying to the fact that the inner shelf was a turbid environment during highstands, perhaps more turbid than today. It is concluded, therefore, that the pre-reef environment was totally different on the inner shelf compared with the outer shelf and that reef initiation was later on the inner shelf compared with the outer. In both cases, however, reef growth was a relatively recent phenomenon.

The drill core at Ribbon 5 and Boulder Reefs testify to the youth of the Great Barrier Reef and to the fact that reefs

have been destroyed and regrown again on at least six occasions on the outer shelf (Figure 11a, R1–R6) and four occasions on the inner shelf (Figure 11b, R1–R4). Coupled with the isotopic data from the ODP cores, it is concluded that sea-level oscillations are the cause of the repeated demise and subsequent reestablishment. Further, the isotopic data also indicate that the initial establishment of the reefs on the outer shelf was climate controlled, and occurred on a rhodolith-dominated bank on the outer shelf. Such subtropical red algal banks may have formed in the way such banks occur on the south Queensland shelf today.

### The modern reef

The history of growth and development of the modern reef has been defined largely by drilling through the reefs into their Pleistocene substrate. Hopley et al. (2007) report 160 drill holes in 50 reefs, and 750 dates. These data indicate that the amount of Holocene reef growth varies from 0 to 28 m (Davies and Hopley, 1983; Hopley et al., 2007). Transects across the northern reefs east of Cooktown and off Townsville indicate little difference in the thickness of reef from west to east (Davies et al., 1985). Longitudinally, however, down the length of the Great Barrier Reef, Hopley et al. (2007) report an increase in thickness from Torres Strait to south of Cairns and then a gradual decrease in thickness to the south. They, therefore, imply a change in the depth of the Pleistocene substrate from north to south and invoke either long or short-term subsidence to explain it. An additional process, hydroisostasy, has also been at work to ultimately define systematic variations in thickness (see *Glacio-Hydro Isostasy*, this volume).

The composition of the Pleistocene substrate has been shown to be reef framework on the mid- and outer shelf, similar or identical to the modern reef. The Pleistocene corals are, however, sometimes accompanied by thick coralline algal crusts and *Halimeda* grainstones as seen at One Tree Reef and Ribbon Reef 5 (Marshall, 1983; Webster and Davies, 2003). On fringing reefs, the Pleistocene is sometimes composed of mud, sand, and gravel (Kleypas and Hopley, 1993). Soil horizons have been reported from Fairfax and Fitzroy reefs in the southern Great Barrier Reef, from Redbill, Hayman, and Davies Reefs in the central region and from Ribbon Reef 5 in the northern region. Soil development implies erosion of the underlying limestone and it is surprising that so few have been reported considering the number of holes drilled. As the age of the Pleistocene substrate has been established in the south at One Tree Reef (Davies and Marshall, 1980; Marshall, 1983) and in the north at Ribbon Reef 5 (International Consortium for Great Barrier Reef Drilling, 2001) as isotope stage 5 (around 125 ka), then sea level is likely to have been +5 m above present sea level. Assuming the stage 5 reef grew to sea level, erosion of up to 33 m must have occurred on reefs in the region (assuming no subsidence). Allowing for

subsidence of 10 m (rapid) in the 100 ka period since exposure of the 125 ka reef, then erosion of up to 23 m will have occurred. The Pleistocene surface on which the Holocene reef has grown is, thus, a much modified (some would say karstified) earlier reef.

### Holocene reef start-up

Holocene sea level in the Great Barrier Reef transgressed the foundations of most Pleistocene platforms in the time frame 7–10,000 years BP (Hopley et al., 2007). Start-up growth occurred after transgression was complete, with 17 out of 22 reefs dated starting growth in the time frame 7,100–9,000 years BP. On the outer shelf start-up began at 6.6–8.6 years BP; in the mid-shelf it was around 9.1–6.9 years BP, while on the inner shelf it was around 7.8–6.3 years BP.

In the Great Barrier Reef, sea level changed from a transgressive to a stillstand condition around 6,500 years BP. The age at which reefs reached sea level broadly depends on the depth of their foundations and these ages are summarized in Hopley et al. (2007). Nearly 60% of all reefs cored and dated reached sea level in the interval 5,000–6,500 years BP meaning that nearly 60% of the reefs studied have been subject to a shallow water energy regime for most of the time that they have been growing. Growth, therefore, must reflect this.

The interactions between growth and sea level prompted Davies and coworkers (Davies and Montaggioni, 1985; Davies et al., 1985) and Neumann and Macintyre (1985) separately, independently, and in different oceans to define five strategies of reef growth in the Holocene:

- Keep-Up Reef growth – reefs growing and keeping pace with sea-level change, such that reef flats developed early. Pleistocene foundations are relatively shallow.
- Katch-Up 1 Reef growth – reefs which started to grow well after inundation but then grew so quickly that they were able to catch-up before sea level stabilized.
- Katch-Up 2 Reef growth – reefs which started to grow well after inundation but did not grow so fast so that catch-up occurred after sea level had stabilized.
- Katch-Up 3 Reef growth – reefs which did not start to grow until after sea level had stabilized so that the growth was into continually shallowing water.
- Screwed-Up (Give-Up) Reef Growth – reefs which died before reaching sea level. Neumann and Macintyre (1985) considered that these were “drowned reefs,” but Davies and coworkers considered other factors could also effect death (turbidity, elevated nutrients, and subsidence).

More than one growth strategy can occur on the same reef as local environment factors affect the growth response (Davies and Montaggioni, 1985; Davies et al., 1985). Further, the rates of growth are depth dependent; thus growth approximates an “S” shaped curve – slow growth to start, rapid growth as the reef grows into shallow water and slow growth again as the reef is subject to high energy in shallow water. Plots of growth rates against paleo-water

depths (Davies et al., 1985) show rates of  $>8 \text{ m/ka}^{-1}$  for water depths of 12–15 m,  $4 \text{ m/ka}^{-1}$  for water depths of 20 m and corresponding low rates in shallow water. This is particularly well seen for the outer shelf reefs and total reef data set in Figure 12. It is not so well seen for the mid-shelf reefs where the shallow water rates of growth are not that much less than the mid-water-depth rates but this may be due to the reduction in energy on the mid-shelf reefs compared to the outer shelf reefs. Surprisingly, growth rates change little with latitude.

### Growth at sea level

When a reef reaches close to a stabilized sea level, it comes under the influence of the ambient hydrologic regime. Three features are produced on most reef types (see below) – the algal and coral reef flat and the sand sheets: rubble flats are found on only a few reefs. The reef flats and the rubble flats are described in detail by Thornborough

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 12** Vertical growth rate data plotted against palaeo water depths (modified after Hopley et al., 2007).

and Davies (Reef flats this volume). Attention is given here, therefore, to the sand sheets which are intertidal and subtidal. In Figure 13, intertidal sand sheets occur on the southern reef flat bordering the lagoon while subtidal sand sheets occur between the rubble banks and the lagoon along the eastern margin. The southern intertidal sand sheet occupies an area of  $822 \times 1,000 \text{ m}^2$  and contains a sand volume of 14 million tones of carbonate. A section through the sand sheet summarizes its major growth features as seen in vibrocores and drill holes and surface maps show its essential granulometric variations (Figure 13c). In Figure 13b a lower subtidal sand overlies rubble close to the junction with the coral flat and is in turn overlain by intertidal sands as the body builds up to sea level. The sand is derived from the windward margin and the outer edge of the coral flat from where it is wave transported on every tide toward the lagoon. The sediments of both units comprise corals, coralline algae, foraminifera, mollusks, and minor *Halimeda*. The subtidal sands are characterized by fining upward rhythms while the upper intertidal sequences are characterized by coarsening upward sequences. However, in both units most stratification is destroyed by shrimp bioturbation. The intertidal sand sheets are prograding into (filling up) the lagoon.

The eastern subtidal sands occur in 3–5 m of water along the eastern junction of the lagoon with the eastern rubble flat (Figure 13a). Surface sediments are very coarse to fine sands and show a decrease in grain size toward the lagoon; cores show fining upward sequences being destroyed by bioturbation. These subtidal sands occupy an area of  $538,000 \text{ m}^2$  and contain approximately 9 million tones of carbonate. They are comprised of uncemented corals, gastropods, foraminifera, corallines, and bivalves derived through bio and physical erosion of the eastern rubble flats.

The distinctive sea-level signatures on almost all reefs in the Great Barrier Reef are the algal/coral flats and sand sheets. Rubble flats occur on only the high energy reefs.

### Types of reefs

The following reef types have grown in the Great Barrier Reef – fringing reefs, mid-shelf reefs (patches, crescentic, lagoonal platform reefs, and flat-topped planar reefs), and outer shelf reefs (detached reefs, deltaic reefs, ribbon reefs, and giganto-reefs) (Maxwell, 1968; Hopley, 1982). For completeness, they are briefly described below. (See entries *Reef Classification by Hopley (1982)*; *Reef Classification by Maxwell (1968)*).

According to Hopley et al. (2007), there are 758 fringing reefs in the Great Barrier Reef Marine Park, but representing less than 2% of the total reef area. Most occur between latitudes 20–22S and most fringing reefs show a weak biologic and morphological zonation. Recent studies describe fringing reefs in turbid inner shelf environments (Perry and Smithers, 2009; Smithers et al., 2006) comparable to the environments postulated above for Boulder Reef off Cooktown.

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 13** (a) Vertical air photograph of One Tree Reef in the southern region. (b) Section through the sand sheet summarizing its major features, and (c) granulometric variations across the sand sheet and lagoon.

Mid-shelf reefs occur throughout the Great Barrier Reef region although the number, shape, and complexity varies substantially. On the basis of size and physical attributes, they are classified as patches, crescentic, lagoonal platforms, and flat-topped planar reefs. Juvenile, mature, and senile varieties of the crescents, lagoonal, and flat-topped reefs have been described (Davies, 1983; Hopley et al., 2007). Critical factors in their evolution are size, depth, and shape of the Pleistocene substrate; the length of time they have been at sea level; and the energy in the shallow water environment.

Outer shelf reefs occur on the shelf edge and are often linear, and aligned parallel to the edge which can be steep or stepped. Detached reefs occur in the northern region eastward of the main reef edge (and therefore detached), particularly east of the Torres Shelf where the Ashmore-Boot-Portlock complex occurs (Figure 14a). They have

grown on pinnacles of continental crust and are fronted by very deep water in excess of 1,000 m, while the moat between the reefs and the shelf edge can be up to 700 m deep and infilled with prograding siliciclastics from the Papuan platform (Figure 14a). Deltaic reefs also occur in the extreme northern region and are made up of short narrow reef segments separated by passes behind which distinctive delta-like patterns have been produced by tidal currents flooding through the passes and on which reefs have grown mimicking the delta-like shapes of the underlying sand substrate (Figure 14b).

Ribbon reefs occur on the shelf edge over a distance of 700 km between 11S and 17S as a series of narrow discrete reefs (10–28 km long) separated by passes up to a kilometer wide. They are numbered sequentially northwards. Probably the best known of the Ribbons is Ribbon 5 (Figure 14c) because there are three drill holes

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 14** (a) Seismic sections across the Ashmore – Boot-Portlock reef complex (b) the northern deltaic reefs (After Hopley et al., 2007), (c) Ribbon reefs of the Pompey Reef complex (After Hopley et al., 2007).

through the Holocene and the deep hole through the total thickness of the Great Barrier Reef (Davies et al., 1985; Webster and Davies, 2003) reported above. The gigantoreefs of the central southern region (Pompey Reefs) are indeed large (Figure 14d). Forming an almost continuous barrier over a shelf edge length of 140 km, many of the reefs are 50–100 km<sup>2</sup> in area, and 15 km long (Hopley, 2006; Hopley et al., 2007). They are surrounded by water depths of 60 m and oceanwards give way to a terrace sloping down to a shelf edge at 100 m. The morphology of this terrace is shown in Figures 14b and 15.

### Growth – the facies produced

Five broad carbonate facies are recognized as occurring in the Holocene reefs of the Great Barrier Reef. Three are framework facies and two are detrital facies:

1. Coralline algal facies are laminated crusts, often centimeters thick, and/or encrustations on branching or massive corals, composed principally of *Mastophoroid* algae either *Hydrolithon onkodes* or *Neogoniolithon fosliei*. Vermetid gastropods and encrusting foraminifera are constant faunal associates. The facies is best

Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 15 Bathymetric profiles across the submerged shelf east of Hydrographer's Passage (From Harris and Davies, 1989).

developed on windward margins, but encrusting coral-lines coat most dead or dying surfaces in all intertidal reef environments.

2. Branching coral facies is comprised essentially of various species of *Acropora*, *Pocillopora*, and branching *Porites*. Growth form varies with depth, light, and energy. In shallow water, variations in energy define wide differences in species composition and diversity. Water-depth changes produce similar compositional variations.
3. Massive (Head) coral facies is comprised mainly of various species of *Porites*, *Goniopora*, *Favia*, *Leptoria*, *Platygyra*, *Symphyllia*, *Leptastrea*, *Goniastrea*, and massive *Acropora*. As with the branching forms, water depth and energy defines diversity.
4. Sand facies is usually medium to coarse sand comprising coral, corallines, benthic foraminifera, and minor *Halimeda*. Occasionally rudaceous-sized fragments are found. Sorting varies depending on distance from source and degree of bioturbation. It forms large sand sheets between coral flats and lagoons and also infills lagoons.
5. Rubble facies is comprised of massive, platey, and branching corals varying in size from 20 kg blocks to finger-like sticks. They are poorly sorted, occupying large intertidal areas, sometimes cemented, often bioeroded; also found in spurs and grooves, and at the base of lagoonal patch reefs. They are produced either by in situ collapse (in lagoons) or by energy-related breakage and transport.

Two non carbonate facies have also been identified but are minor compared with the carbonate facies. These are siliceous muds and clays derived from rivers inputting onto the inner shelf (Davies and Hughes, 1983; Smithers and Larcombe, 2003), and granites as at Lizard Island contributing coarse quartz and feldspar to an otherwise carbonate environment, but with corals actually growing on the granites (Webster, 1994).

### Growth models

Three growth models are presented below for three distinctive reef types defined above as lagoonal platforms, crescent reefs, and ribbon barrier reefs.

#### The One Tree Reef Model

One Tree Reef (Figure 13) occurs in the Capricorn and Bunker Reefs of the southern Great Barrier Reef. Surface sampling and subsurface drilling and coring define One Tree as the best understood reef in the whole region. Three dimensional models show the Holocene One Tree Reef growing atop its Pleistocene foundation and mimicking its shape. In Figure 16a, the Pleistocene is exposed during the lowstand. The highest part of the exposed rim is the algal flat and coral flat because the areas of greatest erosion during the lowstand would likely be the reef front and the sand flat/lagoon margin (see *Antecedent Platforms*, this volume). Transgression would initiate growth on the high rim, after which growth would be to sea level

(Figure 16b). At this point, development of the reef flat, sand sheets, lagoonal patch reefs, and the rubble sheets will grow to the stable sea-level position (Figure 13a). The effect of dominant energy is to produce clear constructional and destructional windward/leeward aspects. Throughout its history different parts of One Tree exhibited keep-up or catch-up strategies.

#### The Stanley Reef Model

Stanley Reef (latitude 19.18S) is a crescent reef in its eastern part and an “almost-atoll” in the west (Figure 16c). All work conducted was on the eastern part which is both similar and very different to One Tree Reef; similar in having a distinct edge to the east and southeast and dissimilar in having a wide open lagoon and a lee edge which is patchy. The reef is highest around the rim along the eastern margin where the Pleistocene is at nearly 15–18 m and on the leeward patches at 20–22 m. A lagoonal patch reef in a lee position showed the Pleistocene at around 20 m. The lagoon is currently deep (+20 m), and assuming 5–10 m of sediment, the Pleistocene in the lagoon would be at a depth of +30 m. During low sea level, Stanley was a crescent with a high eastern rim decreasing in height to the west, and a large open deep basin on the site of a former lagoon and open lee end. Holocene growth on this antecedent surface occurred almost simultaneously on windward and leeward margins (Table 1). At the time of the first dated growth, palaeowater depths on the windward margins were 10–12 m and on leeward edges 14–18 m. The first phase of growth was vertically to sea level, after which, growth of the windward margin replicates that seen on most reefs (see One Tree and Ribbon 5) with the development of a windward reef flat and sand flat. The leeward edge arrived at sea level later than the windward margin. The next phase of growth for this crescent reef is for the leeward patches to coalesce to form a continuous lee edge, at which time, the crescent reef will become a lagoonal platform reef. At this stage, most sediment derived from the windward margin will be trapped in the lagoon leading to an acceleration in the infill of the lagoon (assuming enough time).

#### The Ribbon 5 model

Ribbon 5 (Figures 11a and 17) is a shelf edge barrier reef east of Cooktown for which the database is more complete than any reef in the Great Barrier Reef. It defines both the Pleistocene and the Holocene evolution. The model, defined by data in Figures 11a and 17, has the following elements:

1. Initiation of reef growth on a shelf edge rhodolith bank following a major climate change around 300,000–350,000 years BP.
2. Destruction and regrowth of reefs successively, due to sea-level oscillations, on eroded antecedent surfaces with each reef initiating and growing on or close to the position of the previous reef. A stacked succession of reefs is thus formed (Figure 17b).

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 16** (a) Low stand position shows the pedestal on which One Tree Reef sits. (b) high stand growth of One Tree Reef on its pedestal and (c) Stanley reef - a mid shelf reef in the central reef region. The lithologies encountered in drill holes indicate a framework-dominated windward margin and a sand dominated lee margin. Plots of depth against age show the windward margin getting to sea level first and progressively later backwards.

**Great Barrier Reef: Origin, Evolution, and Modern Development, Table 1** Oldest drill dates and depths from Stanley Reef and calculated sea-level and water depths

| Drill hole | Oldest age | Depth | SL position | Water depth |
|------------|------------|-------|-------------|-------------|
| BMR 1      | 7,500      | 12 m  | −2m         | 10 m        |
| BMR 2      | 8,250      | 16 m  | −4m         | 12 m        |
| BMR 3      | 7,990      | 19 m  | −5m         | 14 m        |
| JCU 2      | 7,010      | 19 m  | −1m         | 18 m        |

- Growth of the Holocene reef occurred first on the windward margin (6,500–7,000 BP) on a Pleistocene substrate at around −15 to 16 m, and progressively later leewards where the oldest date for growth is around 4,500 BP at a depth of about −14 m. The windward margin began to develop its reef flat and shed sand leewards after reaching sea level around 6,000 BP. The leeward margin holes (holes 3 + 4) are dominated by sands which postdate the time at which the windward margin approached sea level.
- Growth of the Ribbon reefs since sea level stabilized has been due to (1) catch-up to sea level by patch reefs that initiated late, and (2) leeward growth of the coral flat (as described for One Tree in Reef Flat Thornborough and Davies this volume), and substantial backward shedding of sand into the leeside environments.

Most reefs in the Holocene, with the possible exception of fringing reefs, have undergone the same basic processes of growth from an antecedent platform to sea level and then growth controlled by the direction and energy of the impinging energy. This is common in the three models defined above. The models are however of two totally different reef growth environments – the shelf edge and the mid-shelf platforms. They are almost two end members with different characteristics produced by the same parameters. In both cases the dominant control is substrate, to produce a linear outer shelf feature and crescentic/lagoonal mid-shelf features. However, in the mid-shelf reefs, Davies (1978), Davies and Marshall (1980), Hopley (1982), Davies (1983), and Davies and Hopley (1983) all recognized patterns of reef development with specific characteristics which appeared to overlap and which could be related to the depth, size, and shape of the Pleistocene substrate, the timing of reaching sea level, and the total energy within the physical environment. Hopley (1982) and Hopley et al. (2007) show similar models for the central reefs. In an evolutionary sense, reefs can be judged to be juvenile, mature, and senile. Thus, crescentic reefs (Stanley, Fitzroy) can grow into lagoonal platform reefs and eventually into flat-topped platforms with live coral growth only around the perimeter. Most importantly, the rate of progress along the evolutionary chain is a function of the size and depth of the platform and the energy impinging in the stillstand system. Thus, small reefs (Wreck in the Capricorns) will progress to senility rapidly while Stanley is yet to achieve maturity. The three reef

types will however be dominated by both different processes and the same processes acting at different rates. This becomes an important issue when considering how reefs will react to climate changes proposed for the next 50 years. As a consequence, for example of increased storminess, mature reefs (and most are) will progress more rapidly to senility in spite of (or rather because of) possible increases in growth potential in areas which are not temperature marginal. The same conditions affecting a senile reef will accentuate erosion leading to possible obliteration of such reefs, particularly if they are small in size.

## Summary

The Great Barrier Reef occupies the passive margin of northeast Australia, and is arguably the largest coral reef system to have ever existed on the planet. It represents one of a series of major architectural features forming the margin – the Eastern, Queensland and Marion Plateaux; the Pandora and Bligh Troughs; the Osprey Embayment; and the Queensland, Townsville, and Cato troughs. Coral reefs occur on all three plateaux in addition to the Great Barrier Reef. Some 3,600 reefs are estimated to form the Great Barrier Reef. The margin architecture seen today is a consequence of rifting, drifting, subsidence, sea-level/climate change, and continental collision. Coral reefs established on three occasions (1) in the early to late-mid-Miocene; (2) in the uppermost Miocene; and (3) in the Pleistocene. The Great Barrier Reef, as it is known, started in the late Pleistocene, as seen in drill core data from Ribbon 5/Boulder Reefs and at ODP site 820. On the outer shelf at Ribbon 5, drill core data show a reef section (0–96 m) above a rhodolith-dominated section (95–158 m) above a packstone/wachestone section (158–210 m). Initial reef establishment of the coral frameworks in the middle of the rhodolith section dates from some time after 465 ka while the firm establishment of the main reef section above 96 m dates from around 300,000 years. At Boulder Reef on the inner shelf, tentative dating places reef start-up at around 210,000 years. Reef initiation is therefore most probably facies controlled and not karst antecedent controlled. The ages and the succession of reefs at Ribbon 5 (six reefs) and Boulder Reef (four reefs) also testify to the fact that reefs have been destroyed and re-grown again on at least six occasions on the outer shelf and four occasions on the inner shelf. The modern Great Barrier Reef is the last expression of regrowth following the last post-glacial transgression. Almost certainly, antecedence has assumed greater relevance through each new growth phase.

The development of the modern reef system is documented through the largest geoscientific reef database for any system in the world (160 drill holes in 50 reefs and 750 dates). Start-up occurred 7–10,000 years BP most often on eroded (karstified) remnants of the previous (125 ka) reef phase. Nearly 60% of all reefs cored and dated reached sea level in the interval 5,000–6,500 years BP meaning that nearly 60% of the reefs studied have been

**Great Barrier Reef: Origin, Evolution, and Modern Development, Figure 17** Ribbon Reef 5 (a) Three dimensional model of Ribbon 5 down to about 25 m and showing the lithologic and radiocarbon dates from drill holes (1–4). (b) The distribution of facies developed in a high energy reef system as a function of successive sea-level oscillations. Facies variations within the successive reefs show backward prograding sedimentological and biological wedges.

subject to a shallow water energy regime for most of the time that they have been growing; growth therefore reflects this. Different reef growth strategies reflect the interaction of substrate depth, sea-level rate of change, and coral growth rate. A major change in growth and bio- and sedimentary facies occurs when the growing reef approaches sea level – the formation of algal and coral flats reflect biofacies changes and sand sheets and rubble flats reflect sedimentary facies changes.

Five broad carbonate facies are recognized; three are framework facies and two are detrital facies:

1. Coralline algal facies. These are laminated crusts, often centimeters thick and/or encrustations on branching or massive corals. The facies is best developed on windward margins, but encrusting corallines coat most dead or dying surfaces in all intertidal reef environments.
2. Branching coral facies. Growth form varies with depth, light, and energy. In shallow water, variations in energy define wide differences in species composition and diversity. Water-depth changes produce similar compositional variations.
3. Massive (head) facies. As with the branching forms, water depth and energy define diversity.
4. Sand facies. These are usually medium to coarse sand comprise coral and corallines, benthic foraminifera, and minor *Halimeda*. Forms large sand sheets between coral flats and lagoons and also infills lagoons.
5. Rubble facies. These are comprised of massive, platy, and branching corals. Produced either by in situ collapse (in lagoons) or by energy-related breakage and transport.

Three growth models are presented, two for mid-shelf platform reefs (One Tree and Stanley Reefs) and one for outer shelf barrier reefs (Ribbon 5). It is concluded that most Holocene reefs in the Great Barrier Reef, with the possible exception of fringing reefs, have undergone the same basic processes of growth from an antecedent platform to sea level and then growth controlled by the direction and energy of the impinging energy. This is common in the three models defined above. The models are however of two totally different reef growth environments – the shelf edge and the mid-shelf platforms. They are almost two end members with different characteristics produced by the same parameters. In both cases, however, the dominant control is substrate, to produce a linear outer shelf feature and crescentic/lagoonal mid-shelf features. However, in the mid-shelf reefs, patterns of reef development are recognized which have specific characteristics which appear to overlap and which are probably related to the depth, size, and shape of the Pleistocene substrate, the timing of reaching sea level, and the total energy within the physical environment. In an evolutionary sense, reefs can be judged to be juvenile, mature, and senile. Thus, crescentic reefs may grow into lagoonal platform reefs and eventually into flat-topped platforms with live coral growth only around the perimeter. Most importantly,

the rate of progress in this evolution is a function of the size and depth of the platform and the energy impinging in the still stand system. Thus, small reefs (Wreck in the Capricorns) will progress to senility rapidly while Stanley (large reef) is yet to achieve maturity. Evolutionary progression may occur through more than one highstand growth phase. Predicted future climate changes will accelerate evolutionary progression.

## HALIMEDA

---

Edward Drew  
Townsville, Queensland, Australia

### Synonyms

*Siphonales* (in older literature); *Siphonous* algae

### Definition

*Halimeda* is a genus of warm temperate to tropical macroalgae classified into

Phylum: *Chlorophyta*  
Class: *Bryopsidophyceae*  
Order: *Bryopsidales*  
Family: *Halimedaceae*  
Genus: *Halimeda*

### Phytochemistry

#### Photosynthetic pigments

*Halimeda* chloroplasts contain the characteristic photosynthetic pigments of the Chlorophyta, plus *siphonoxanthin* and *siphonoin*, which are specific to the Bryopsidales.

#### Cell wall

*Halimeda* and most other Bryopsidales have cell walls composed of a **xylose-based  $\beta$ -1–3 linked xylan**, not the glucose-based cellulose found in all other Chlorophyta.

#### General

Author's *Halimeda* Web site:

<http://members.iinet.net.au/~edrew1/halimeda/halimeda.htm>

### Appearance

*Halimeda* thalli are composed of branching chains of calcified green segments joined together by flexible, uncalcified nodes. The thalli may be erect, pendant, or sprawling. They may grow up to 25 cm high or cover over 1 m if sprawling. They are anchored by holdfasts, which may be

- (i) A small basal mass about a cm long, consisting of matted rhizoidal filaments adhering to rocks.
- (ii) Or a large, dense bulbous mass, 1–13 cm long, buried in the sediment. It consists of fine rhizoids with adhering sediment particles and can be up to 40% of the plant's total weight.
- (iii) Or several diffuse, inconspicuous patches of rhizoids arising at intervals from segments or nodes of the algae sprawling on rocks or unstable surfaces.

Segment size and shape vary considerably between species. They may be flat, keeled, or even cylindrical in some. Their outline varies from ovate to cuneate and may be distinctly lobed. The width varies from 2 to 55 mm.

### Taxonomy

*Halimeda tuna*, from the Mediterranean Sea, is the holotype of the genus. It was first described, but named *Sertolara*, by Imperato (1599). During the next century, it was given several different generic names and was considered to be a coralline animal. In 1812, it was finally recognized as a plant and given its currently recognized binomial name, *Halimeda Tuna* (Ellis and Solander, 1786; Lamouroux, 1816). At that time, exploration of tropical regions had just begun, and the number of described *Halimeda* species reached 26 by 1887, most species being described solely on the basis of their segment morphology.

Currently, 44 species are recognized, distinguished using the morphological and anatomical characters

introduced by Barton (1901) and expanded by Hillis (1959); Hillis-Colinvaux (1980) also defined five distinct taxonomic Sections within the genus, based on anatomical details of the uncalcified nodes (see also “Internal structure” below).

Molecular systematics, first applied to the genus by Hillis et al. (1998) and expanded by Kooistra et al. (2002), yielded (i) a well-resolved phylogeny, (ii) confirmation of the five lineages, but requiring some re-organization, and (iii) demonstration of high cryptic species diversity, most tropical *Halimeda* species found consisting of two distantly related, genetic entities, which are indistinguishable by current methods of morpho-taxonomy. Verbruggen (2005) provides a detailed account of recent taxonomic progress within the genus.

### Distribution

*Halimeda* is a warm water alga well represented in the tropics, mainly on coral reefs. There is one species, *H. cuneata*, which is strictly subtropical, while a genetically distinct form of the tropical species *H. tuna* is the only species found in the temperate Mediterranean Sea.

Of the 30 species then recognized by Hillis Colinvaux in 1980, 77% occurred in the Indo-Pacific Region and 46% in the Western Atlantic Region (Caribbean). Of the 13 species in the Caribbean, seven also occurred in the Indo-Pacific. The remaining six endemic species are presumed to have evolved after the rise of the Isthmus of Panama closed the Central American Seaway, separating the Western Atlantic from the Pacific in the Miocene (circa 3.5 Ma ago).

On coral reefs, *Halimeda* can occur from protected lagoons to the shallowest reef flat environments, exposed seaward reef fronts and as deep as 140 m on fore reef slopes (Hillis-Colinvaux, 1985; Littler et al., 1986) (see also “Contribution to carbonate sediments” below).

While *Halimeda* is the only genus in the family *Halimedaceae*, it is closely related to the larger family *Udoteaceae*, which contains several other calcified, green macro algae, such as *Udotea*, *Penicillus*, and *Rhipocephalus*. These are often conspicuous in *Halimeda* habitats, as are several species of the closely related, but uncalcified, genus *Caulerpa* (family *Caulerpacaeae*).

### Internal structure

*Halimeda* segments consist of a central medulla of intertwining, branched, and sometimes anastomosing siphons (medullary filaments) running the length of the segment. These segments, with their large vacuoles, are continuous throughout the plant with a central few forming the uncalcified nodal region, a flexible joint between the segments. Within the nodes, the walls of the filaments may become thickened, fuse for part of their length, and even develop connecting pores, but there are no cross walls anywhere in the plant. The entire thallus is thus one multinucleate cell and is described as a **coenocyte**.

Near the segment surface, the medullary filaments branch vertically to form a cortex consisting of up to four layers of variously inflated utricles. The top layer (the primary utricles) is closely packed and appears polygonal in surface view. The size, shape, and branching patterns of these utricles are important taxonomic characters (Hillis-Colinvaux, 1980).

### Growth

Individual *Halimeda* thalli grow by producing new segments. These develop from small tufts of medullary filaments, which grow out from the distal perimeter of a segment at or near the tip of a branch. This process begins in the afternoon and the tuft of filaments becomes organized into a new soft, uncalcified segment overnight. This new segment is initially white, but by dawn it is bright green. A few hours after dawn it is whitish green, having already begun to calcify (see also “Diurnal color change (ii)” below). Fast growing branch tips can produce a new segment every few days.

### Calcification

The calcium carbonate endoskeleton is laid down in the internal spaces between the medullary filaments forming the segments. This is a light-driven process, requiring only that the superficial utricles contain functional chloroplasts and are closely adpressed, effectively isolating the interfilamental spaces from the external seawater. This happens within 36 h of initiation of the new segment.

Thereafter, whenever photosynthesis occurs, the resulting removal of CO<sub>2</sub> from the water in the interfilamental spaces raises its pH and causes deposition of calcium carbonate as aragonite crystals (Borowitzka and Larkum, 1976).

The overall degree of calcification varies (i) between species; (ii) within the algal thallus, with the lower, older segments more calcified than those at the growing tip; and (iii) with water depth and levels of irradiance.

### Diurnal color change

*Halimeda* thalli become almost white after dark and then green again by next morning. This is due to mass relocation of chloroplasts, and probably other organelles, from the peripheral utricles into the medullary filaments. There they remain, hidden beneath the calcium carbonate endoskeleton, until re-emergence begins a few hours before dawn. This mass relocation of organelles, which can only occur because of the coenocytic structure of the thalli, involves an extensive cytoskeleton of microtubules and actin fibers and will consume a considerable amount of energy every day (Drew and Abel, 1990; 1992). This energy-intensive endogenous rhythm may, however, give *Halimeda* crucial advantages in the dynamic coral reef environment, including

- (i) **Daily** – minimization of grazing damage because chloroplasts and other organelles are protected within the calcium carbonate endoskeleton when surface-scraping grazers are most likely to be active.

Rapid paling of the green segments also occurs in response to damage during the day.

- (ii) **Every few days** – relocation of chloroplasts beyond their parent segment allows the new segments, which develop overnight, to be populated with functional chloroplasts before dawn, via the nodal filaments. This allows calcification to start in the new segments at first light, rather than awaiting subsequent activation of its proto-chloroplasts by light-dependent *de novo* synthesis of chlorophyll.
- (iii) **Only once – immediately before death** – facilitation of rapid overnight redistribution of the entire contents of the medullary filaments into the superficial gametangia in preparation for holocarpic sexual reproduction (see also **Reproduction** below).

### Grazing

*Halimeda* is often found in abundance in areas on coral reefs where herbivorous fish exert high grazing pressure, but it is among the least preferred food items there. This is probably because of the high levels of calcification, a major physical defense against predation. In addition, the new segments, which are very vulnerable until calcified, are always produced at night when grazing pressure is low (Hay et al., 1988).

*Halimeda* also has chemical defenses against grazing. It synthesizes two secondary natural products, the diterpenoids halimetatetracetate and halimeditrial, which have considerable grazing deterrence properties, but are also potentially toxic to *Halimeda* itself. However, although both are present at high concentrations in the young, uncalcified segments, only reduced concentrations of the less toxic halimetatetracetate occur in the older segments, which are now heavily calcified, and so less vulnerable (Paul and Alstyne, 1988a).

Although these mechanisms can help to minimize grazing on *Halimeda*, it can still be heavily grazed, especially on seaward reef fronts where the lower parts of thalli, which have been severely cropped by herbivorous fishes are often found in inaccessible crevices. Once parts of a *Halimeda* thallus have been damaged, its coenocytic structure makes it vulnerable to catastrophic loss of cell contents. However, constrictions at branching points in the medullary filaments, and between the layers of cortical utricles, can quickly become plugged by organelles flowing toward the leak. This will retain the cell contents while the rapid wound repair processes temporarily seal the damaged area within a minute and construct a new wall within an hour (Menzel, 1988).

A very specific and widespread grazer on *Halimeda* is *Elysia halimedeae*, a small Saccoglossan Ophistobranch mollusc. It is a surface scraper completely undeterred by the diterpenoids, which help keep other grazers away. Instead, it actually modifies and accumulates the deterrent chemicals up to 7% of its body weight and then, when irritated, it secretes a defensive mucilage containing them (Paul and Alstyne, 1988b).

*Elysia halimedeae* is about 20 mm long and extremely cryptic as it is exactly the same color as the plants it feeds on. This is because it uses modified radula teeth to harvest intact chloroplasts from the outer utricles of *Halimeda* and stores them in specialized “digestive cells” within its body. This process is called **kleptoplasty**. The chloroplasts are unable to divide within the animal but can continue to photosynthesize and supply it with nutrition for weeks or even months (Trench, 1973; Evertsen et al., 2007). A number of other saccoglossan molluscs also use chloroplasts from other bryosidalean algae such as *Caulerpa* and *Codium*.

Another small animal closely associated with *Halimeda* is the crab *Huenia heraldica*, which grazes on the filamentous epiphytes growing on the segments. It is about 25 mm long, green in color, and has a wide, segment-like carapace. It does graze on *Halimeda* itself to a limited extent, removing segments, and holding them in small specialized claws on its upper body to complete its camouflage.

### Reproduction

*Halimeda* plants bearing gametangia were first reported by Derbes and Solier (1856) and Schmitz (1880). Both also reported the release of biflagellate zooids, although these were not demonstrated to be gametes until Nasr (1947) reported sexual fusion. However, collection of fertile plants has been so infrequent that Hillis Colinviaux (1980) still considered sexual reproduction to be of minor significance in the production of new *Halimeda* plants compared with asexual cloning involving rhizoidal runners and also the continued growth of dispersed plant fragments.

The paucity of field observations of sexual reproduction in *Halimeda*, even after the advent of scuba diving, is probably because it is completed in only 36 h. Healthy green plants transfer their entire protoplasm overnight into large numbers of newly formed, stalked bunches of gametangia that developed on the edges and surface of the segments the day before. The segments themselves are empty and white by dawn. These conspicuous green gametangia mature during that first day and explosively release their contents as gametes soon after dawn on the following day. This can produce a spectacular green soup of gametes in an aquarium tank, leaving a white thallus that is dead and soon disintegrates into a pile of calcified segments.

This process, whereby the plant dies after the whole thallus has taken part in simultaneous conversion of the entire cell contents to gametes, is called **holocarp**y.

Sexual reproduction in *Halimeda* is anisogamous and dioecious, two types of gametes being produced, each on different individuals. The larger “female” macro-gametes are bright green and contain a distinct red eyespot while the smaller ‘male’ microgametes are golden green and have no eyespot (Hillis-Colinviaux, 1980). Gametangia-bearing material is now known for most *Halimeda* species and gamete release and fusion have been reported upon in several, but development of zygotes has only been studied in the laboratory in one species, *H. tuna* from the

Mediterranean (Meinesz, 1980). Development was reportedly very slow and had not progressed beyond a small, uncalcified filamentous plant after 13 months. The characteristic *Halimeda* plant is presumed to be a haploid gametophyte, but it is not known when meiosis occurs, leading to speculation that a second, spore-producing, phase may be involved.

Some species of *Halimeda* may reproduce sexually at species-specific times of the year, while synchrony between field and laboratory populations, and also over considerable areas of *Halimeda* meadows, has been observed on the Great Barrier Reef (Drew and Abel, 1988b).

Recent observations show conclusively that sexual reproduction in seven species of *Halimeda* as well as 15 other Bryopsidalean algae from four genera, is an organized and pervasive phenomenon of coral reefs (Clifton and Clifton, 1999). It is comparable in synchrony and precision with the mass spawning of the corals themselves. Mass spawning of these green algae is also equally spectacular, releasing so many gametes that visibility on shallow reefs can be greatly reduced. Unlike the corals, however, in which entire populations spawn simultaneously on a single day, and live to spawn again next year, only a small part of the algal populations spawn each day, so that spawning can continue for several months, but the participating plants die and the population is progressively reduced. The lifespan of *Halimeda* thalli may be only months, to a maximum of a year, depending on species.

### Contribution to carbonate sediments

*Halimeda* segments may be shed intermittently by living plants or *in toto* after holocarpic sexual reproduction. They contribute much to the structure of coral reefs and atolls as they accumulate between the branching framework produced by the corals themselves. In some reefs, they also cascade down steep fore-reef slopes to form thick sediment deposits on the seabed (Freile et al., 1995).

In the outer lagoon of the Great Barrier Reef, *Halimeda* can also form extensive “meadows” between reefs, growing atop mounds of *Halimeda*-rich gravels, which have been deposited *in situ* by the meadows themselves (Drew and Abel, 1988a). The substratum, of loose dead segments, is stable enough to support *Halimeda* vegetation dominated by the same lithophytic species found on nearby coral reefs, rather than species with holdfasts better adapted to soft substrata. The individual mounds are typically 200–300 m in diameter, coalescing laterally to form 30 m thick banks several kilometers wide. These banks are easily identified by their sinusoidally undulating surface and characteristic seismic signature. They are usually associated with up-welling of cooler, nutrient-rich water from below the thermocline in adjacent oceanic waters (Wolanski et al., 1988), and have accumulated since the

underlying carbonate rock was exposed during the last low sea-level event 10,000 years ago. They have actually grown faster than the nearby coral reefs. Pinnacles of the underlying Pleistocene-age bedrock frequently occur in the hollows between the mounds of *Halimeda*-rich gravels (Phipps et al., 1985). Similar *Halimeda* banks have been found in Indonesian waters (Phipps and Roberts, 1988).

The banks closely resemble geological structures known as “bioherms” – dome-shaped structures composed mainly of the remains of one type of animal or plant (Marshall and Davies, 1988). Fossilized *Halimeda* bioherms are known from India, the Caribbean, and Spain. The latter form part of aerially exposed reefs and are described as “segment reefs.”

### Fossil Halimeda

The unlithified banks of *Halimeda*-rich gravels described above are potential precursors of the carbonate wackestones, rocks composed mainly of fossilized *Halimeda* segments, which occurred in fossil reefs as far back as the early Jurassic, circa 190 Ma ago. The carbonate structure is often very well defined and the rocks are relatively porous, due to voids between the loosely packed segments deposited *in situ*. There are also micro-voids within the segments reflecting the internal anatomy of the algae themselves.

These deposits are very similar to much earlier calcareous fossil algae (collectively known as Phylloid algae), which are widespread in ancient reefs in many parts of the world. Here, their considerable porosity has often allowed the accumulation of hydrocarbons (Wray, 1977).

## HALIMEDA BIOHERMS

Peter J. Davies  
 University of Sydney, Sydney, NSW, Australia

## Introduction

*Halimeda* Bioherms – two words with separate biological and geological connotations – have been used cojoined since 1985 by Davies and Marshall (1985) and Orme (1985) to describe Holocene mounds (bioherms) of dominantly *Halimeda* derived carbonates in water depths generally deeper than 30 m (sometimes 20 m) and forming undulating banks. Some confusion does exist within the literature, not because colleagues do not understand the use of the above authors but because of other discipline-related terms coined and used both before and since 1985. The geological understanding of Bioherm, therefore, needs to be clarified, as does its relations to a term coined at the same time – Biostrome – and their likely

(possible?) relation to the more recently coined biological term, Meadows. For these reasons, it is proposed to very briefly clarify as follows:

First, *Halimeda* are green calcareous precipitating algae from the phylum Chlorophyta in the order Bryopsidales and in two families – Halimedaceae and Udoteaceae. The taxonomy is described by Hillis-Colinvaux (1980) and in the Great Barrier Reef in various papers by Drew and Abel (see references in Drew and Abel, 1988a, b). There is no confusion over the term *Halimeda*, only sometimes over the identification of species.

Secondly, Bioherm is a geological term coined by Cummings (1932) to describe both bedded and nonbedded lens-like or mound-like accumulations, comprised of the often in situ accumulation of invertebrate organisms. The original definition had reefs in mind, invoking topographic relief above the sea floor, an in situ framework and rapid accumulation. In a modern sense, the bioherms described in this entry are not reefal, yet they are mound-like, often with significant relief above the surrounding sea floor and with internal characters, which are bedded or nonbedded and composed of in situ and derived biologic accumulations that have accreted rapidly. In a geological sense, mound-like structures sometimes show substantial mud and few framework organisms (many Carboniferous mounds) and are still legitimately termed bioherms. In the original definition, Cummings (op cit) distinguished bioherms from related structures termed Biostromes (see review by Kershaw, 1994), defined as nonreefal flat bedded structures often but not necessarily comprised of organic accumulations. It is noted here because Orme (1985) and Orme et al. (1978) rightly pointed out that in the northern Great Barrier Reef, large areas of the mid shelf behind the Ribbon Reefs (termed “back-reef” by Orme op cit) appear to be comprised of crudely bedded laterally extensive nonmounded “biostromal sediments” and are associated with *Halimeda* Bioherms (called “banks” by Orme et al., 1978). Later, Drew and Abel (1988a) described the surface characters of such areas as “Meadows” and Hillis-Colinvaux (1988), in a reef lagoonal environment, postulated that Meadows might evolve into Bioherms.

In the present contribution, *Halimeda* Bioherms are used to denote mounds showing relief above the surrounding sea floor and built by the in situ accumulation of *Halimeda* together with other infauna. They are sometimes called Banks (Orme and Salama, 1988) although Banks should rightly be reserved for much larger structures, for example, Bahama Banks. In the Great Barrier Reef and elsewhere, *Halimeda* Bioherms are associated with often larger areas having an extensive sheet-like form and called Biostromal areas (Orme and Salama, 1988, p. 136), the surface of such areas are called *Halimeda* Meadows by Drew and Abel (1988b). Thus, the origin of biostromes (a 3-D geologic term) might be elucidated by studying their surface “Meadows” (a 2-D biological term). Further, the origin of the Bioherms might be determined through studies of the spatially related Meadows/

**Halimeda Bioherms, Table 1** The species diversity of *Halimeda* meadows compared to adjacent reefs in the Great Barrier Reef region

| Species               | Meadows | Reefs   | Conclude                             |
|-----------------------|---------|---------|--------------------------------------|
| <i>H. opuntia</i>     | 0.6%    | 40.2%   | Reef dominant                        |

| <i>H. macroloba</i>   | trace   | present | Meadows and reefs at very low levels |

Biostromes. This entry follows this treatment. First however, the biology of *Halimeda* Bioherms and their related meadows are briefly reviewed.

### The biology of *Halimeda* bioherms and adjacent meadows (biostromes)

*Halimeda* are a green alga that belongs to the phylum Chlorophyta in the order Bryopsidales. *Halimeda* are described by Hillis-Colinvaux (1980, 1988) as being either Rhipsalian and possessing a holdfast or non-Rhipsalian and possessing none or a limited holdfast. In the modern environment, *Halimeda* occur as an accessory component of reefs, or as principal components of bioherms and meadows.

*Halimeda* Bioherms generally occur above a base line of 50 m water depth while meadows generally occur below this depth. The most extensive publications on their biology are those of Drew and Abel (1988a, b). The species composition of bioherms and meadows in the Great Barrier Reef is shown in Table 1.

Species diversity is high. A total of 12 *Halimeda* species, 2 *Udotea* and 1 *Penicillus* occur in water depths above 50 m dominated by the non-rhipsalian *H. opuntia* and *H. hederacea* while in water depths greater than 50 m, only *H. copiosa* and *H. hederacea* occur. Growth occurs via multiple obscure holdfasts restricted to the surface of the sediments. In other areas of the Pacific and Indian Oceans where *Halimeda* bioherms and meadows have been described, the same species predominate. Accumulations of *Halimeda* as meadows have also been reported from the lagoon of Enewetak atoll

**Halimeda Bioherms, Figure 1** Distribution of *Halimeda* bioherms in the Great Barrier Reef. They occur in three areas, Northern reef region, Lizard Island to Cooktown, and in the Swains reefs region.

(Hillis-Colinvaux, 1988) where the dominant species are the rhipsalian *H. incrassata* and *H. cylindrica*.

### The global distribution of *Halimeda* bioherms

#### The Great Barrier Reef

*Halimeda* Bioherms have been described in two areas: (1) two parts of the northern GBR and (2) in the Swains region of the southern GBR (Figure 1).

In the northern Region, *Halimeda* Bioherms have been described by two separate groups in the Lizard Island – Cape Flattery region and in the Ribbon 2–Ribbon 7 region.

The Lizard Island – Cape Flattery region (Figure 1) has been described by Orme and coworkers (Orme et al., 1978; Orme, 1985; Orme and Salama, 1988). They report that 26% of the total shelf area (effectively the outer shelf area behind the shelf edge reefs) between latitudes 14.27S and 15.02S is occupied by *Halimeda* litho-facies (Bioherms and Biostromal meadows). *Halimeda* bioherms are up to 19 m thick and sit on a prominent seismic reflector assumed to be the transgressed pre-Holocene/Pleistocene unconformity. The bioherms (= banks in Orme and Salama, 1988) that rise to within 25 m of current sea level are best developed in the eastern part of the region and their surface is mounded and “cloaked by *Halimeda* meadows – and

a limited veneer of reef coral – especially in troughs.” Little sedimentologic data on the *Halimeda* sediments and no dating have been published.

The bathymetry, seismic structure, submersible examination and photography, sedimentology, and biology of *Halimeda* banks in the region east of Cooktown (Figure 1) have been described by Davies and coworkers (Davies and Marshall, 1985; Phipps, Davies and Hopley, 1985; Marshall and Davies, 1988). They report that between 15.10S and 15.35S in the lee of Ribbons 2–7, the “reefless” tract supports a luxurious growth of *Halimeda* that during the Holocene have developed *Halimeda* bioherms in water depths between 30 and 50 m.

In the southern Great Barrier Reef region, *Halimeda* bioherms have been reported from the Swains reefs region, west of Frigate Shoals in water depths of 20–32 m (Figure 1) (Searle and Flood, 1988).

### The Sahul shelf

On the Sahul Shoals, *Halimeda* are integral components of large “banks” such as Big Bank, Snow White, Happy, Grumpy and Udang (Rees et al., 2007). The banks are generally flat topped with few bioherms in the sense of those described from the Great Barrier Reef.

### The Java Sea bioherms

In the Java Sea, Phipps and Roberts (1988) describe *Halimeda* bioherms on K Bank in the eastern part of the Makassar Straits (Figure 3). They are similar to those described from the Great Barrier Reef, if not a little larger.

### The Miskita bank/channel bioherms

Several generations of *Halimeda* bioherms occur on the shelf northeast of Nicaragua (Figure 4), as seen mainly on multichannel seismic sections.

### Descriptive features of *Halimeda* bioherms

In the Great Barrier Reef, *Halimeda* bioherms occur over large areas behind the outer reefs, as “fields” or “complexes” of inter-fingering or inter-merging individual elongate bioherms, 150 m long (N–S) and 100 m wide (W–E), slightly flat topped and sloping away in all directions at 5–15° (Figure 5a). The most striking surface feature is a forest of soft green algae, sometimes 50 cm thick on the tops and thinning down the sides of each bioherm. This forest is dominated by various species of *Caulerpa* and *Halimeda*. Structurally, it is similar to rain forest in that there is a thick undergrowth on a sandy/gravelly surface, a middle layer of less dense cover and a top canopy. This forest is an ephemeral feature, appearing and disappearing within months. Mollusks, foraminifera, and bryozoans form integral and important parts of the epifauna with *Halimeda*. These collectively mantle the surface of the

top and sides of the bioherms but stop suddenly 3–5 m above the troughs between adjacent bioherms.

Seismic data shows in the Great Barrier Reef and the Java Sea, the bioherms are up to 15 m thick in the GBR (Figure 5a, b + c) but are substantially thicker (+20 m) in the Makassar examples (Figure 5d). In the northern Great Barrier Reef, the bioherms sit on a prominent seismic reflector (Figure 5a + c) which dips from around 33 m immediately west of the reefs to around 65 m some 5–10 km west of the reefs. The bioherms themselves also decrease in size and increase in depth in the same direction. The reflector in Figure 5a + c, is a leached skeletal, limestone whose vugs are partially filled with soil. The geometry of the bioherm complexes bear no relation to the geometry of the prominent reflector. A similar seismic reflector also underpins the bioherms in the Makassar Straits (Figure 5d).

Bedding is the commonest internal structural feature (Figure 5a–d); internally bioherms are sometimes bedded, sometimes transparent and often multigenerational. Individual bioherm complexes show bedding suggestive of several generations of growth. Tops are frequently seismically transparent. Sometimes, there are two seismic facies – a lower indistinctly bedded unit that merges laterally with a biostromal sheet facies and an upper bedded facies forming the upper two thirds of the banks.

Sedimentologically, as seen in cores (Figure 6), the bioherms are comprised of *Halimeda* sands and gravels in an olive green matrix. Large foraminifera, *Marginopora vertebralis* and *Alveolinella quoyi* are subordinate but important parts of the gravel fraction, as are mollusks and bryozoans. The *Halimeda* are dominantly *H. opuntia*, *v. hederacea*, and *H. copiosa* with subordinate amounts of *H. fragilis*, *H. discoidea*, and *H. gracilis*. Texturally the bioherms are gravelly, sandy muds throughout but with slight textural variations down the core. At the surface, the gravel fraction (largely *Halimeda*) comprises 50%, this dropping to 20–30% within 1 m of the top. Deeper in the core the gravel fraction either remains at 20–30% or drops even further to less than 10%. The sand fraction in most cores stands at 20–30% and is comprised dominantly of broken *Halimeda* leaves with contributions also from foraminifera, bryozoans, and mollusks. Mud in the cores measures around 10% in the top half meter of the cores and then increases substantially to between 30 and 50% throughout the rest of the core. Approximately half of this mud fraction is carbonate and half non-carbonate or terrigenous (quartz, kaolinite, and smectite). However, in the Swains Reefs bioherms, the mud matrix is totally carbonate and devoid of terrigenous material, reflecting the distance of these bioherms from the Australian mainland. In the Java Sea, Phipps and Roberts (1988) describe the bioherms as disarticulated *Halimeda* plates with a fine grained matrix of foram-rich carbonate mud (usually less than 40%), only a small percentage of which is non-carbonate (volcanic shards and siliceous spicules). In some cores, *Halimeda* plates form a disorientated open-textured accumulation. Locally, within cores, sediments

**Halimeda Bioherms, Figure 2** *Halimeda* bioherms in the region of the Sahul Shoals, Timor Sea.

are composed of coarse *Halimeda* plates, some of which are still unbroken. Occasionally, layers 5–10 mm thick are comprised of *Halimeda* plates orientated parallel to the bioherm surface.

#### Rates of growth of *Halimeda* bioherms

Biologic studies report a wide range of growth rates for *Halimeda*, varying from  $420 \text{ g CaCO}_3 \text{ m}^{-2} \text{ year}^{-1}$  in the Florida Straits to  $2,234\text{--}3,000 \text{ g m}^{-2} \text{ year}^{-1}$  in the Great Barrier Reef (Drew, 1986). The high rates in the GBR are attained by the plant doubling the biomass of the colony every 15 days. This represents an enormous production of carbonate sediments indicating that *Halimeda* are a major contributor to tropical marine environments. The bioherms described in this entry are testimony to that conclusion. Radiocarbon dating (Table 2) provides some indication of the vertical accumulation rates of the bioherms in the Great Barrier Reef and Makassar Straits.

Table 2 indicates clearly that accumulation rates have been similar in both the Great Barrier Reef and in the Makassar Straits. Depending on porosity, accumulation

rates of close to 3 m/1,000 years are very close to Drew's estimates and confirm that not only are *Halimeda* significant contributors to reef ecosystems, but that they are capable of producing geologically significant ecosystems in their own right.

#### Relations between bioherms (banks) and meadows (biostromes) and the lagoonal meadows at Enewetak

In the Great Barrier Reef, Bioherms are intimately associated with widespread crudely bedded areas which are not mounded and which have been described by Drew and Abel (1988a) as Meadows. Such areas occupy a range of water depths but often deeper than 50 m and extending down to 96 m in places. Similar deposits are reported to occur extensively over K bank east of Makassar Straits. The growth of such features and their relations to the truly biohermal deposits is, therefore, pertinent to the current discussion. Clues as to growth were defined at Enewetak by Hillis-Colinvaux (1988) where various ages of thalli (successional development) were observed to spread

**Halimeda Bioherms, Figure 3** *Halimeda* bioherms in the Java Sea, in the region of the Macassar Strait (After Phipps and Roberts, 1988).

across unconsolidated sediment producing a raised terrace above neighboring barren sands. First, an extensive holdfast system developed together with buried thalli; secondly, *Halimeda* plates were shed and they and associated sediments were stabilized by cyanobacterial

algal mats; thirdly, elevation of thalli above the sediment surface anchored by the holdfast system with further in situ accumulation of plates and platelets and further stabilization by mats; fourthly, the development of an associated flora and fauna, particularly sponges and fifthly,

**Halimeda Bioherms, Figure 4** *Halimeda* bioherms on the Nicaraguan shelf in the region of the Miskita Channel (After Hine et al., 1988).

a thickness was achieved by continuous shedding from perennial growth and algal mat development. This may define a mechanism of growth applicable to the early stages of meadow development of the transgressed Pleistocene surface. However, Drew and Abel (1988a) showed that shallow meadows in the Great Barrier Reef are comprised of non-Rhipsalian algae without strong holdfasts. Further work is required to determine whether such meadows grow out of meadows like those at Enewetak.

### Growth of *Halimeda* bioherms

A number of features are pertinent to growth and origin:

1. They grow from a prominent surface defined in the Great Barrier Reef as the transgressed Pleistocene surface. A similar reflector also occurs below the Makassar Strait bioherms and is also interpreted as the Pleistocene transgressed surface. The shape of biohermal mounds bears no relation to any minor relief

features on this transgressed surface. There is little antecedence effect.

2. They occur intimately associated with sheet-like bedded biostromal deposits (Meadows).
3. In the Great Barrier Reef they occur in the lee-shelter of the Holocene outer barrier.
4. At least in the Cooktown region, they are largest close to the outer barrier, becoming smaller to the west.
5. They are comprised of in situ and derived accumulations of *Halimeda* leaves and an associated fauna of foraminifers, bryozoans, and mollusks, which form a series of multigenerational mounds, sometimes bedded, sometimes transparent.
6. In the Great Barrier Reef and in the Makassar Strait, their presence on the same Pleistocene surface that underlies the modern reefs, places their age as post Pleistocene, growing at the same time as the Reefs. Radiocarbon dating corroborates this conclusion.

The relations (if any) of Bioherms to the Biostromal meadows has intrigued many. Orme et al. (1985, 1988) and Davies and co-workers (1985, 1988) have drawn attention to the co-occurrence of bioherms and biostromes (meadows) and Davies and coworkers in particular cite a variety of evidence (seismic, bathymetric, and visual observations from submersible) to indicate that meadows grade into biohermal areas. In the Great Barrier Reef, a case can be made, therefore, to suggest that meadows (biostromes) first occupied the transgressed Pleistocene surface and evolved into bioherms in places favorable to vertical growth. However, the development of a vertical growth potential demands special conditions and Davies et al. (op cit) and Drew and Abel (1988b) point to the likely importance of enhanced nutrients as an essential requirement. Thompson and Wolanski (1984) proposed that strong tidal currents operating in the inter-reef channels produce a Bernoulli Effect, lifting off-reef water onto the shelf through passes deeper than 50 m. Further Wolanski et al. (1988) propose that off the Cooktown region, upwelling and development of a tidal jet is occurring and carrying nutrient rich water from a reef passage to the *Halimeda* meadows. Such upwelling is limited to channels shallower than 45 m. These mechanisms add substantial weight to the timing and modes of origin defined by Davies and Marshall (1985) and summarized in Figure 7.

### Significance of *Halimeda* bioherms

Originally the term "bioherm" was coined and used by petroleum geologists, particularly in an exploration sense, to describe features that did or could contain petroleum. Thereafter, it became synonymous with "reef-like" structures and important targets in petroleum exploration. Davies et al. (1988) described *Halimeda* bioherms as potential exploration targets in the Australian region. More recently, however, Davies and Marshall (1985) pointed out a different and perhaps more significant

**Halimeda Bioherms, Figure 5** (a) West to east seismic section across the outer Cooktown shelf showing bedded nature of the *Halimeda* banks in 30 m of water. (b + c) Uninterpreted and interpreted seismic section across the banks on the outer Cooktown shelf. The multigenerational nature of the banks together with their planar Pleistocene growth surface clearly visible. (d) Seismic section of thick *Halimeda* banks in the Makassar Strait, Java Sea. The banks are clearly sitting on a planar surface interpreted as the Pleistocene.

**Halimeda Bioherms, Figure 6** Cores from the *Halimeda* banks on the Cooktown shelf. The positions of detailed photographs are shown on the cores.

feature of *Halimeda* bioherms in the Great Barrier Reef at least, that is, they produce  $3 \text{ kg CaCO}_3 \text{ m}^2 \text{ year}^{-1}$  compared to 3–4 kg for the reefs; however, the bioherms occupy a larger area. They may, therefore, lock up a greater proportion of  $\text{CaCO}_3$  than do the reefs. Since the correlation between carbon dioxide ( $\text{CO}_2$ ) levels and global temperatures was established in the ice core records, this conclusion assumes an even greater significance because it indicates not only the relevance of calcareous algae as important additional  $\text{CO}_2$  sinks but when

estimated on a global basis it also doubles the contribution of shallow water carbonate sediments (in conjunction with reefs) as  $\text{CO}_2$  reservoirs (Rees et al., 2007).

### Summary

*Halimeda* bioherms have been described from three parts of the Great Barrier Reef: from the Sahul Shelf, from the Makassar Straits, and from the Nicaraguan Bank. They form mounds that are up to 20 m height and are comprised of the skeletal remains of various species of *Halimeda*

**Halimeda Bioherms, Table 2** Vertical accumulation rates of bioherms in the Great Barrier Reef and Makassar Straits

| Region   | Location   | Exact position | Ages (years BP) | Sed rate           |
|----------|------------|----------------|-----------------|--------------------|
| GBR      | North bank | 0–5 m          | 270–2,760       | 2 m/1,000 years    |
| GBR      | Big bank   | 0.4–2.8 m      | 270–1,300       | 2.33 m/1,000 years |
| GBR      | Big bank   | 2.8–5.4 m      | 1,300–4,750     | 0.75 m/1,000 years |
| Java Sea | PC 12      | 0–100 cm       | 0–1,000         | 1 m/1,000 years    |
| Java Sea | PC12       | 100–250 cm     | 1,000–1,250     | 0.6 m/1,000 years  |
| Java Sea | VC 4       | 0–250 cm       | 0–1,250         | 0.2 m/1,000 years  |
| Java Sea | VC 4       | 250–450 cm     | 1,250–2,000     | 2.7 m/1,000 year   |

**Halimeda Bioherms, Figure 7** Origin of *Halimeda* bioherms as proposed by Davies and Marshall (1985). The key to growth are strong nutrient eddies produced by jets of upwelled oceanic waters flooding through the inter-reef passes before the modern reefs began in the time frame 11–9,000 ka (a + b). *Halimeda* banks grew well in this time frame. However, when the Pleistocene substrate was topped by the rising sea level (c) nutrient concentrations were not delivered specifically to the banks but, generally, to the leeward environments. Bank growth may have slowed down at this point. However, when the Holocene reefs reached sea level, flow into the back reef was again forced through the passes, leading to more nutrient availability and a spurt in the growth of more banks (d). Thus multigenerational growth relates to nutrient flux.

(*H. opuntia*, *v. hederacea*, and *H. copiosa* with subordinate amounts of *H. fragilis*, *H. discoidea*, and *H. gracilis*) together with large benthic foraminifera, mollusks, and bryozoans. The bioherms are bedded, sometimes transparent and often multigenerational, and sit astride the late Pleistocene transgressed surface. They have grown at the same time as the adjacent reef ecosystem and at rates almost equivalent to the reef systems. This suggests not only a critical relevance of calcareous algae as important additional CO<sub>2</sub> sinks but when estimated on a global basis it also doubles the contribution of shallow water sediments (in conjunction with reefs) as CO<sub>2</sub> reservoirs.

## HAWAIIAN EMPEROR VOLCANIC CHAIN AND CORAL REEF HISTORY

---

Richard W. Grigg  
 University of Hawaii, Honolulu, HI, USA

### Definition

The palaeoceanography of the Hawaiian Emperor volcanic chain of islands and seamounts and the presence of coral reefs share an incomplete history. The first known Hawaiian Island to emerge from the Hawaiian hotspot was Meiji Guyot approximately 70+ Ma ago. Today, movement of the Pacific Plate has transported Meiji Guyot from its original location at approximately 19° north latitude and 157 west longitude almost 6,000 km to the northwest to about 54° north latitude, to a location near the edge of the juncture of the Kuril and Aleutian trenches, virtually on the edge of subduction below the Asian Plate (Figure 1). Unlike all of the islands in the Hawaiian Archipelago today, Meiji Guyot was never surrounded by a coral reef. Present theory, if correct, holds that the first half of the Hawaiian Emperor history was devoid of coral reefs (Grigg, 1988). Several explanations have been advanced to explain their apparent absence during this early period of Hawaiian history.

However, before discussing the palaeoceanographic evidence for the early absence of coral reefs in Hawaii, it

is first important to reiterate the chronological, geographic, and geochemical evidence that shows that all of the Emperor Seamounts and Hawaiian Islands in the chain originated from the same hotspot in the North Pacific (Wilson, 1963; Morgan, 1972). Perhaps the best evidence for a common origin of the volcanoes over the Hawaiian hotspot is the continuous age progression (K-Ar radiometric dates) of the volcanic edifices with distance from Kilauea (location of the present hotspot) (Jackson et al., 1980, Figure 4). Relatively continuous motion of the Pacific Plate at about 8 cm/yr over the Hawaiian hotspot during the last 70+ Ma resulted in the formation of an almost linear geographic chain of volcanic islands. A bend in the chain at approximately 43–50 Ma is explained by a shift in the direction of plate propagation from north to northwest. The geo-chemical evidence for Hawaiian volcanoes and the Emperor Seamounts also supports the common origin hypothesis. All the lavas exhibit a similar sequence of eruption (tholeiitic followed by alkalic basalts) as well as similarities in chemical composition of all the basalts (Fletcher et al., 2008; Rooney et al., 2008).

The claim that coral reefs were absent in the Hawaiian chain during the first half of the Tertiary rests on the fossil record of shallow marine organisms in the Hawaiian Emperor (H-E) Chain today. The oldest reef corals that have been recovered from dredged limestones and deep-sea drilling cores in the Emperor Seamounts and guyots, range between 21 and 34 Ma. The oldest samples (33 and 34 Ma) are specimens of *Porites* and *Astreopora* from Kanmu and Yuryaku Seamounts (Grigg, 1988). The biostratigraphy based on cores from the older and more northern Emperor Seamounts (Ojin, Nintoku, Suiko, and Meiji) consists primarily of a tropical biofacies of shallow warm water coralline algae, bryozoa, benthic foraminifera, ostracods, spirorbids, echinoid spines, bivalves, and brachiopods, but no reef building corals (Jackson et al., 1980). Possible causal factors for their absence could be sampling error, a more northerly position of the palaeo-Hawaiian hotspot, cooler sea-surface temperatures in the Paleogene, rarity of corals worldwide in the early Tertiary, or insufficient transport of coral larvae from the Indo-West-Pacific (IWP). While a combination of these factors could also explain the early absence of coral reefs in the history of the H-E chain, the theory that is best supported by the palaeoceanographic history of the Pacific Ocean, is isolation of the Hawaiian Archipelago from the IWP (Grigg, 1988). All of the fossil corals and all of the reef corals that exist in the H-E chain today are IWP in origin, although some endemism (~25%) has evolved over time.

During the middle Tertiary, a series of gradual palaeoceanographic changes, including closure of the Tethys Sea, development of thermohaline circulation, isolation of Antarctica, and intensification of latitudinal temperature gradients are believed to have combined to intensify gyral circulation in the North Pacific Ocean (Kennett, 1982). As a result, the Kuroshio Current in the Western Pacific and the Subtropical Counter Current would have

**Hawaiian Emperor Volcanic Chain and Coral Reef History, Figure 1** Cutaway of the earth showing the location of the Hawaiian hotspot and the Hawaiian-Emperor chain of islands and seamounts from Hawaii in the southeast to Meiji Guyot at the juncture of the Kuril and Kamchatka trench subduction zone.

strengthened and both are sources of transport of IWP coral larvae into the northern Pacific Ocean. Hence, the sudden appearance of reef corals in the Hawaiian Archipelago and their continual presence throughout the Neogene to the present day might best be attributed to ocean circulation. Even today, the coral fauna of Hawaii is highly attenuated and consists of less than 10% of the coral species now present in the IWP.

Although the fossil record shows that reef corals have been in the Hawaiian Archipelago since Mid-Oligocene time, a moderate degree of taxonomic turnover has occurred. Extinction and re-colonization events are particularly evident in the Midway core from the present all the way back to early Miocene time (Wells, 1982). This is not surprising, nor unexpected, given the northerly position of the Hawaiian Islands near the latitudinal limits of reef building corals as well as their relative isolation from island stepping stones to the south and west.

Today, approximately 59 species of reef building corals have been recognized in the main Hawaiian Islands while 57 are reported in the Northwestern Hawaiian Islands (NWHI), (Maragos et al., 2004). These totals, while significant, are still relatively depauperate compared to the IWP where about 700 species are reported to exist (Veron, 2000). The low species diversity of modern Hawaiian reef building corals underlines the significance of the isolation of the Hawaiian Archipelago, as well as, its northerly latitude. The effect of latitude is particularly important when applied to the growth rate of individual corals.

Using *Porites lobata* as a proxy for all other common reef corals in the Hawaiian Archipelago, Grigg (1982, 1997, 2008) showed that growth rates at the southeastern end of the chain are typical of tropical coral growth rates in general, while moving northwest in the chain, they decline in a linear fashion almost as a direct function of latitude (Figures 2 and 3). At the very end of the Archipelago, at a latitude of  $\sim 29^\circ$  north at Kure Atoll, the net growth rate was found to be virtually zero if losses due to bio-erosion, mechanical erosion, and the subsidence rate of the island were all taken into account. If this fact is considered over geological time in combination with the northwesterly movement of the Pacific Plate, then subsequent drift of the atoll to the northwest would cause it to gradually drown, setting the northern limit (threshold) of atoll formation (Grigg, 1982). In recognition of Darwin's original theory of atoll formation (Darwin, 1842), Grigg labeled this threshold "The Darwin Point".

Looking at coral reefs today in the Hawaiian Archipelago, they span about  $10^\circ$  of latitude stretching from optimal environments in the southeast to those in the northwest at the extreme limits of coral reef growth. Considering the natural constraints associated with this geography, most Hawaiian reefs today are exceptionally healthy. The most common natural disturbance events are large episodic waves that abrade and scour the reefs (Dollar, 1982). Within the major high Hawaiian Islands from Hawaii to Kauai, the most significant anthropogenic impacts include sedimentation events from land runoff,

**Hawaiian Emperor Volcanic Chain and Coral Reef History, Figure 2** Colony accretion of *Porites lobata*, coral cover, and reef accretion on seaward reefs off all major Hawaiian Islands. Note that coral reef accretion goes to zero near 29° north latitude.

eutrophication in areas of confined circulation, particularly in shallow water bays and on reef flats, and widespread over-fishing of reef fish on practically all offshore reefs. There is an urgent need to strengthen the enforcement of fish and game regulations by the State of Hawaii. The State should also actively increase the number of Marine Protected Areas (MPA's) in the main islands where today only about 1% of the coastline is protected. In contrast, the NWHI have been almost completely protected under a recent (2006) Executive Order that reclassified the entire area (except Midway Island) as a Marine Monument.

## Outlook

Looking ahead toward the present century, particularly with regard to global climate change (GCC), coral reefs in the Hawaiian Archipelago may be relatively well situated. The four most important factors associated with GCC that may affect coral reefs are sea-level rise, increases in sea surface temperature, increases in ocean acidification, and increased storminess. Rising sea level may pose a flooding problem for the lowest isles in the northwest but it will also raise the "lid" providing more accommodation space for coral reef growth to take place on most island shelves throughout the chain. Given the northern latitude of

**Hawaiian Emperor Volcanic Chain and Coral Reef History, Figure 3** Schematic figure of the Hawaiian-Emperor chain showing Zones 1–4 tracing the evolution, subsidence, drowning, and subduction of volcanic edifices and the location of the Darwin Point and northern limit of drowned guyots (From Scott and Rotondo, 1983).

the Archipelago, rising sea surface temperature may not be as great a problem as it could be for more tropical reefs. Although effects due to increasing ocean acidification are not well understood, large carbonate deposits that exist throughout the Archipelago may buffer the potential impacts of slightly lower pH. Increased storminess is also hard to predict depending on frequency, magnitude, and location, but if larger wave events are produced, then intermediate disturbance may become more limiting to coral development and abundance. Overall, while it may be premature to predict dire consequences for the health of coral reefs globally, the coming century clearly contains as many challenges as it does uncertainties.

## HEAVY METAL ACCUMULATION IN SCLERACTINIAN CORALS

Sofia Shah, Edward Lovell  
 University of South Pacific, Suva, Fiji

## Synonyms

Heavy metals are also referred to as trace metals or trace elements

## Definition

Heavy metals are metals and metalloids, which have atomic weights between 63.5 and 200.6 g/mol and density  $> 4.5 \text{ g/cm}^3$  (Shah, 2008). Heavy metals are conservative in nature as they persist in the environment for longer periods. Heavy metals are both naturally occurring and anthropogenically introduced in the marine environment and are toxic to both aquatic biota and humans at low concentrations.

## Heavy metals in the marine environment

Elevated concentrations of the heavy metals are the consequence of effluent discharge, urban stormwater, sewage pollution, harbor dredging, sedimentation, and agricultural and industrial runoff. According to Al-Rousan et al. (2007), these heavy metals occur in the coral skeletons as a result of structural incorporation of metals into the aragonite (Goreau, 1977), inclusion of particulate materials in skeletal cavities (reviewed by Howard and Brown, 1984), surface adsorption onto exposed skeleton (St. John, 1974; Brown et al., 1991), and chelation with the organic matrix of the skeleton (Mitterer, 1978). Once incorporated into the coral skeleton, the metals will remain embedded forever since the new growth covers the old carbonate surface (St. John, 1974).

## This study

The metals of interest in this study were copper (Cu), zinc (Zn), lead (Pb), cadmium (Cd), and iron (Fe). Cu, Zn, and

Fe were of particular interest as they are the essential elements required for growth of organisms as well as humans. On the other hand, Cd and Pb, being the non-essential elements, are harmful to the marine organisms due to their polluting effects and toxicity. The concentrations of these metals together with the partitioning of these metals in the skeleton, tissue, and zooxanthellae of three different coral families were looked into. Heavy metal accumulation rates were also studied in the three different families for a 5-day period. Coral samples were taken from three different sites, namely reefs encountering significant terrigenous inputs from rivers, fringing reefs (with a chain of hotels), and a pristine reef.

## Scleractinian corals

*Scleractinian* corals are the architects of coral reefs and hence good indicators of environmental changes due to the fact that their skeletons assimilate records of the presence and concentrations of certain metals over centuries (Esslemont, 1999). Scleractinian corals incorporate the trace elements (or heavy metals) in their living parts and skeletons. *Acropora formosa*, *Pocillopora damicornis*, and *Porites spp.* were studied for heavy metal concentrations.

## Outcomes

High metal concentrations were determined for the zooxanthellae, than the tissue and the skeleton, suggesting that the zooxanthellae are responsible for the metal uptake in corals. Reichelt-Brushett and McOrist (2003) suggest that symbiotic zooxanthellae play an important role in the accumulation and regulation of trace metals. The variation among the three different families of corals suggests that *Porites spp.* tend to accumulate lower concentrations of heavy metals than the other two species studied. Scleractinian corals in pristine environments recorded a lower metal concentration than those obtained from fringing reefs and reefs closer to significant terrigenous inputs.

Fe and Pd were found to be in higher concentrations than Cu, Zn, and Cd at all the study sites. The most probable reason that Fe reaches the marine environment is through suspended sediments and aeolian dust. Fringing reefs and reefs near terrigenous inputs have constant influences of suspended sediments and hence it is most likely that Fe enters the marine environment through this means. High concentrations of lead in the samples were mostly from sewer outfall, industrial discharge, and agricultural/storm water runoff and wastes discharged from hotels and piggery farms.

Dose-response curves from the bioassays showed that as the nominal concentrations increase, the heavy metal uptake in corals also increases. Zooxanthellae were lost to the aquaria water as a result of stress on the corals. High concentrations of Pb and Fe were accumulated in the corals for each dosage period.

## HISTORICAL ECOLOGY OF CORAL REEFS

---

John M. Pandolfi  
The University of Queensland, Brisbane, QLD, Australia

### Definition

Historical ecology: Using time-series data collected over single or multiple temporal scales to lend insight into the history of modern communities and ecosystems.

### Introduction

The diversity, frequency, and scale of human impacts on coral reefs are increasing to the extent that reefs are threatened globally (Wilkinson, 2008). The direct and indirect effects of overfishing and pollution from agriculture and land development have been the major drivers of massive and accelerating decreases in abundance of coral reef species (Moberg and Folke, 1999; Abram et al., 2001; Jackson et al., 2001; Gardner et al., 2003; Hughes et al., 2003; Pandolfi et al., 2003). These human impacts and the increased fragmentation of coral reef habitat are unprecedented and have the possibility to undermine reef resilience (Bellwood et al., 2004), raising the likelihood that modern coral reefs might be much more susceptible to current and future climate-change than is suggested by

their geologic history (Hughes et al., 2003; Bellwood et al., 2004).

One of the most urgent questions in conservation science is: What was natural in the world before humans impacted it? Study of past ecosystem condition and the relationship between ecosystem health and human–ecological interactions provides a way to gain insight into what was natural in the sea. Historical ecology is the name generally given over to such study. It provides a basis for avoiding the “shifting baseline syndrome” (Pauly, 1995) which undermines current perspectives on what constitutes a pristine ecosystem.

The conceptual framework surrounding historical ecology finds its roots in Aldo Leopold who in 1941 called for study of wilderness areas, for “. . . a science of land health needs, first of all, a base-datum of normality, a picture of how healthy land maintains itself. . .” (p. 3). Several papers on terrestrial ecosystems in the early 1990s have set the tone of historical ecology (Morgan et al., 1994; Swetnam et al., 1999). In general, historical ecology links past ecosystem condition with the present state using time series data over a number of temporal scales, from decades to millennia, though shorter term studies conducted over discrete time intervals can also be used. Insights generally sought over the long temporal frames of historical ecology include changes in states of populations, species, and ecosystems (e.g., abundance, biomass, geographic ranges), changes in environmental parameters (e.g., sea surface temperature fluctuations), and changes in magnitudes and rates of both biological (e.g., mortality rates, trophic flows, disturbance regimes) and physical (e.g., El Niño–Southern Oscillation, climate change) processes.

### The tools of marine historical ecology

Practitioners of marine historical ecology on coral reefs use a number of different kinds of data from multiple time periods to examine the recent past history and present condition of reef ecosystems to provide a natural baseline for community ecology and coral growth rates. Archaeological sites provide insight into the relationship between the development of civilization and its evolving impact on coastal marine resources. Historical records such as those found in ships logs, and publications of early naturalists and European colonialists provide a moving window of the natural history and inferred ecology of many coral reef inhabitants. Fisheries records and modern ecological surveys can be used in association with remote sensing data (going back the last 20 or 30 years) to provide a detailed picture of changing environments and biodiversity as human population and consumption, as well as economic globalization, have accelerated during the past several decades. Taken together, these databases provide a holistic view of changing environments and ecology on coral reefs that includes the onset of human disturbances and against which the acquisition of present day data can be evaluated.

Paleontological (Aronson and Precht, 1997; Wapnick et al., 2004; Pandolfi and Jackson, 2006), archaeological (Erlandson and Rick, 2008), historical (Starkey et al., 2000; Bolster, 2006; Lajus, 2008), ecological (Greenstein et al., 1998; McClenachan et al., 2006), genetic (Roman and Palumbi, 2003; Alter et al., 2007), and modeling studies are all contributing to a new awareness of the past bounty and diversity in the sea (Jackson, 2008; Pinnegar and Engelhard, 2008). Historical data sources include oral histories (Dulvy and Polunin, 2004), photographs (McClenachan, 2009), museum records (Robinson and Frid, 2008), early scientific studies (Lajus et al., 2007), fisheries information including logbook data (Klaer and Polacheck, 1997), landings, effort, and gear (Bager et al., 2007; Lotze, 2007; MacKenzie et al., 2007), and fishing charts (Claesson, 2008). Historical studies are limited to the periods of time and geographic areas for which data are available (MacKenzie et al., 2007). Some studies are limited to more recent history (McClenachan, 2009), while others date back to the sixteenth century (MacKenzie et al., 2007). Many fisheries records are only available for disjointed time periods (Gaumiga et al., 2007; MacKenzie et al., 2007), while others provide continuous time series lasting over a hundred years (Holm and Bager, 2001; Lajus et al., 2007). Some data sources provide only a snapshot of past conditions such as journal entries and photographs; however, when viewed together over a period of time such information can reveal substantial changes in marine environments (Jackson, 1997).

### Historical ecology of coastal ecosystems

Recent papers on the historical ecology of coastal ecosystems have demonstrated the importance of time-series data to understanding the ecology and degradation over long temporal scales. For example, by employing a multi-disciplinary approach involving ecologists, oceanographers, archaeologists, and social scientists, Jeremy Jackson and his colleagues (Jackson et al., 2001) investigated the ecological history of coastal ecosystems worldwide. The work documents in broad terms the history of human alterations in the sea, identifying overfishing as the first and farthest reaching cause of decline in coastal marine ecosystems. Historical marine ecology has since investigated a broad range of ecosystems and problems in the sea (for recent review see Lotze and Worm, 2009).

### Key findings on coral reefs

Study of coral reef ecosystems has also been subject to the “shifting baseline syndrome” – coral reef systems have undergone systematic degradation prior to recent ecological studies in the last three or four decades. This strongly implies that no reef can be considered “pristine”, and that no standard exists by which to compare the magnitude of these changes (Jackson et al., 2001). Through paleoecological reconstruction of coral reefs from the Caribbean region, recent studies have highlighted the collapse of coral communities at a regional level, which is unprecedented

within the Holocene (12,000 years ago – present), (Greenstein et al., 1998; Aronson et al., 2002) and Pleistocene (1.8 million – 12,000 years ago), (Jackson, 1992; Greenstein et al., 1998; Pandolfi, 2001; Pandolfi and Jackson, 2006).

Very recent work has sought to understand human impacts by developing time-series data archives that can be used to evaluate trends in the global decline of coral reefs since the arrival of humans (Pandolfi et al., 2003; Daley et al., 2008). Study of the historical ecology of coral reefs, relying on the past history of corals and other components of the reef ecosystem showed that the history of ecosystem changes among 14 different tropical reef sites worldwide, with early and effective overfishing as the major culprit in reef decline (Pandolfi et al., 2003; Pandolfi et al., 2005). These findings point to the immense importance of understanding historical events when attempting to tease out factors that have influenced or may influence present coral reef biodiversity (Pandolfi et al., 2003). By considering these global “ecological trajectories” in the light of potential responses to projected global climate change, the history of human exploitation can be linked with global environmental parameters (Hughes et al., 2003). Knowledge of past ecosystem states provides at the minimum, an understanding of what was natural and may even aid in assessing the success of management toward particular conservation goals.

Numerous other smaller scale studies have been undertaken on individual reefs and reef areas around the world, including Hawaii (Herman, 1979), the Great Barrier Reef, (Daley et al., 2008), Florida (McClenachan, 2009), Bahamas (Blick, 2007), Solomon Islands (Aswani and Hamilton, 2004), Indonesia (Palomares et al., 2007) and the Caribbean (Jackson, 1997; McClenachan et al., 2006). The demise of many coral reef fisheries has been traced to their historical beginnings including Florida sponges (McClenachan, 2008), Caribbean turtles (McClenachan et al., 2006) and monk seals (McClenachan and Cooper, 2008), sea turtles in Oceania (Allen, 2007), and Hong Kong fisheries (Cheung and Sadovy, 2004). Through these studies, there is now general recognition throughout the coral reef scientific and management communities of the importance of considering changes in ecosystem state over appropriate time scales (Dulvy and Polunin, 2004; Knowlton and Jackson, 2008; Pinnegar and Engelhard, 2008). Importantly, there is far greater appreciation of the historical development, timing, and ecosystem responses to the ultimate drivers of coral reef ecosystem decline, namely overfishing (Roberts, 2007), climate change (Hughes et al., 2003), and coastal development and pollution (Ramade and Roche, 2006).

An understanding of the history of reef coral communities can aid conservation initiatives by supplying information on natural baselines in the sea that are immune to the “shifting baseline syndrome”. For example, in Barbados coral community composition was very similar during four separate reef-building episodes between 220 ka and

**Historical Ecology of Coral Reefs, Figure 1** Non-metric multi-dimensional scaling (NMDS) ordination of the relative abundance of the common coral taxa in Pleistocene and modern assemblages from Barbados, West Indies. (a) Coral assemblages aged 104, 125, 195, and 220 ka from the Pleistocene leeward reef crest of Barbados. (b) Combined analysis of Pleistocene and modern coral assemblages surveyed in the 1980s by Tomascik and Sander (1987) (from Pandolfi and Jackson, 2006).

104 ka (thousand years ago) (Pandolfi and Jackson, 2006), and community structure is now very different in modern degraded habitats (Lewis, 1960, 1984; Tomascik and Sander, 1987) (Figure 1). The same six most common coral species comprise >97% of the total coral density in the fossil assemblages: *Acropora palmata*, *A. cervicornis*, organ-pipe *Montastraea*, *M. annularis* s.s., *Diploria strigosa*, and *M. faveolata*. *Acropora palmata* was overwhelmingly the most abundant species at all four time periods. In marked contrast to the Pleistocene coral assemblages, those from the living reef on Barbados are dominated by species that were rare in the Pleistocene communities. The most abundant coral is *Porites astreoides*, followed by *P. porites*, *Siderastrea radians*, and *Agaricia agaricites*. Living communities contained very little *A. palmata* and no *A. cervicornis*. Similar contrasts between ancient and modern assemblages have also been derived from reef framework cores taken from the nearshore Great Barrier Reef (Perry et al., 2008; Pandolfi et al., 2009).

### Management implications

The descriptive side of marine historical ecology has been vigorously pursued, especially after the publication of Jackson et al. (2001). This has been confined mainly to admonitions about how resources “then” were unimaginably greater than they are “now” (summarized in Lotze and Worm, 2009). But marine historical ecology has lagged behind its terrestrial counterpart (Swetnam et al., 1999; Froyd and Willis, 2008) in harnessing the enormous scope and information potential of direct import to the understanding and management of marine environments. This has resulted in several disadvantages to coral

reefs and our understanding of them: (1) management without a temporal context; (2) a diminished ability to differentiate between chronic and cumulative impacts; (3) uncertainty in attributing ecological changes to human or natural agency; (4) encouraged equilibrium views of ecosystem dynamics; and (5) difficulty in setting management goals and assessing the effectiveness of management actions.

The challenge for natural resource managers is in understanding where the ecosystem they are managing stands in relation to its natural state. Historical knowledge of ecosystems is critical for understanding natural variability and temporal dynamics and provides an essential bridge between science and management goals and outcomes. More positive outcomes are possible when managers possess clear goals for ecosystem restoration derived from knowing how different today’s oceans are from their pristine condition.

### Summary

Seascapes, nearly anywhere you care to investigate, have undergone undeniable transitions from “nature-dominated” to “human-dominated” regimes (Figure 1). Knowing the nature and timing of these transitions cannot be attempted outside of a historical context. How do humans interact with seascapes? How long ago was this interaction first detectable? Lengthening the temporal scale of ecological studies affords the opportunity to debate the characteristics of the transition from nature to human-dominated seascapes along slowly changing gradients. It is also of critical importance to reef management for (1) identifying drivers of ecosystem change, (2) providing meaningful goals for successful management and a means for measuring success of management actions, and (3) adopting a dynamic view of ecosystems.

## HOLOCENE HIGH ENERGY WINDOW

---

Chris Perry  
 Manchester Metropolitan University, Manchester, UK

## Definition

*Holocene high energy window*: A period of higher wave energy conditions across submerged reef or continental

shelf environments that was caused by reef growth lagging behind rising sea levels during the Holocene transgression.

## Introduction

The concept of a Holocene “high energy interval” or “window” was first introduced by Neumann (1972) as a mechanism to explain the emplacement of relict sedimentary deposits that appeared to have formed under higher energy conditions than those prevalent in the present. Specifically, it was suggested that these deposits might have formed during periods when coastlines were less protected than at present. This concept was subsequently developed by Hopley (1984) as a potential control on the nature and character of shelf sedimentary environments, using Australia’s Great Barrier Reef (GBR) shelf as an example. Such temporal changes in energy conditions are believed to have occurred in settings where the outer shelf or barrier reefs failed to keep pace with rising sea levels during the Holocene transgression. Rather they adopted “catch-up” (*sensu* Neumann and Macintyre, 1985) growth trajectories, with the lag interval providing a depth window through which waves could propagate across both developing reef surfaces and wider shelf sedimentary systems. The legacy of this is seen today as the occurrence of high energy sedimentary deposits that could not have formed under present energy regimes. As reef growth reached present sea-levels the “window” was progressively shut resulting in reduced wave energy conditions to leeward of reef crests or across open shelf environments and a consequent transition in styles of reef growth and sediment accumulation.

## Global and regional scale perspectives

The potential for the occurrence of a high energy window during the Holocene transgression was entirely controlled by the interactions that occurred between the rate of coral reef growth and the rate of sea-level rise. These interactions must, inevitably, have differed between reef sites and on a regional basis, and thus the potential for the occurrence, and longevity of any higher energy periods must have been spatially very variable. For example, in the Caribbean region, reconstructed Holocene sea-level curves show that rates of sea-level rise have steadily fallen since ~10,000 years BP (when sea level was at ~–24 m below present) through to the present day. Rates of rise averaged ~5.2 mm year<sup>–1</sup> up until ~8,000 years BP, ~1.5 mm year<sup>–1</sup> from about 8,000 to 4,000 years BP, and 0.93 mm year<sup>–1</sup> from 4,000 years BP to present (Toscano and Macintyre, 2003). Taking a modal long-term rate of reef accretion of ~6–7 mm year<sup>–1</sup> (e.g., Montaggioni, 2005) most reefs would have had the potential to track rising sea-levels (“keep-up” growth mode: *sensu* Neumann and Macintyre, 1985), thus minimizing the potential for the development of a high energy window (Figure 1a). In contrast, rates of sea-level rise during the early phases of the Holocene transgression were much faster in much of the Indo-Pacific basin (Camoin et al., 2004).

**Holocene High Energy Window, Figure 1** Regional variations in the potential for the existence of a Holocene high energy window for (a) the Caribbean, and (b) the Indo-Pacific regions (based on sea-level curves from the central Great Barrier Reef Shelf, Australia). Note that under scenario (b) reef growth lags a rapidly rising sea level, providing a window for high wave energy propagation across the shelf.

In eastern Australia, for example, where Hopley (1984) discussed the potential for the development of periods of high energy conditions during shelf flooding, sea-levels during the early-mid Holocene are estimated to have been rising at  $\sim 10 \text{ mm year}^{-1}$  from about 9,000 to 7,500 years BP, and then at  $\sim 2\text{--}2.5 \text{ mm year}^{-1}$  through to  $\sim 6,000$  years BP when sea levels slightly exceeded their present day position. Since this, highstand sea-level has fallen to its present level. This faster rate of sea-level rise during the early-mid-Holocene period is believed to have resulted in reef growth lagging behind sea-level, thus temporarily allowing higher wave energy regimes to propagate across reefs and the inundating shelf environments (Figure 1b). However, as plots of sea-level position against reconstructed reef growth trajectory plots demonstrate, the potential for the development of a high energy window appears very variable even at an intra-regional scale (Camoin et al., 2004).

The existence of such a high energy window has been most widely discussed in relation to the GBR shelf of Australia (Hopley, 1984; Hopley et al., 2007), although the timing and existence of such a window probably varied at different points along the shelf. This has been viewed, in large part, as a function of variations in the depth from which Holocene reef growth was re-establishing - those areas with deeper Pleistocene foundations having greater potential to adopt catch-up growth modes as they lagged behind sea-level (Hopley et al., 2007). For example, along

the northern and southern sections of the GBR reef establishment occurred above foundations at depths of  $\sim 15\text{--}20 \text{ m}$  and the high energy window is inferred to have been open only for a relatively short period of time between  $\sim 8.0$  and  $6.0 \text{ ka}$ . In contrast, the greater depth ( $\sim 20\text{--}25 \text{ m}$ ) of the Pleistocene foundations in central areas of the GBR means that the window may have been open for longer. In this area of the shelf, the occurrence of relict Pleistocene reefal substrates along the shelf margins is believed to have protected the newly submerging shelf from high wave energy conditions prior to  $\sim 9,000$  years BP (Figure 2). However, from about 8,500 years BP these relict reef structures were progressively over-topped as newly established outer-shelf reef growth lagged behind rapidly rising sea levels. The result was a marked increase in energy levels across the newly submerged shelf, with important impacts on mainland coast and shelf sediment dynamics. Significant onshore transport of coarser-grained sediments is believed to have occurred during this period, and has been cited as a causal factor in the deposition of high energy features such as boulder beaches and spits around some of the inner-shelf high islands (illustrated in Hopley et al., 2007, fig 7.4). Also during this time significant onshore migration of reworked terrigenous shelf sediments is believed to have occurred, producing the presently well-defined inshore terrigenous sediment prism (Larcombe and Woolfe,

**Holocene High Energy Window, Figure 2** Schematic diagram showing the influence of a Holocene high energy window on the development of shelf environments based on the central Great Barrier Reef region of Australia (stage concepts developed from Hopley, 1984; Hopley et al., 2007).

1999). During the final stages of the transgression, when present sea-levels were reached (or exceeded), reefs along the outer-shelf margin caught up with sea-level, leading to closure of the high energy window. Numerous headlands were incorporated into the coast during the final stage of the transgression resulting in the development of a much more indented coastline. This facilitated the trapping of longshore-driven sediments and the development and progradation of extensive coastal beach ridge sequences.

### Impacts of a high energy “window” at the reef and reef island scale

Whilst the concept of a Holocene high energy window is perhaps best known from discussions regarding its influence on the GBR shelf, the concept has also been considered in relation to different phases of reef and reef island development. This is evident, for example, along

reef-fronted coastlines and narrow shelves where reef growth appears to have lagged behind sea-level. Subsequent accumulation of barrier-type reefs up to sea-level resulted in a closure of these more localized high energy windows, leading to a transition in the nature and character of reef-building to leeward of the main reef structures. Examples include those reefs described from the Ryukyu Islands (Kan et al., 1997), Palau (Kayanne et al., 2002), and Madagascar (Camoin et al., 2004). The concept of high energy phases has also been discussed as an important potential control on reef island building. Kench et al. (2005), for example, have invoked periods of higher wave energy and associated sediment transport to nodal sites of accumulation, as an important control on the development of reef islands in the Maldives. Similar views have also been discussed in relation to a range of reef islands in the Pacific (Nunn, 1997) and on the GBR (Hopley, 1984).

## Summary

The concept of a Holocene high energy window has been evoked to explain the presence of sedimentary deposits that appear to have formed under higher wave energy conditions to those operating in the present. Such periods of higher energy can occur where vertically accreting reefs lag behind rapidly rising sea levels – thus opening up the potential for wave energy to propagate across both reef structures and adjacent shelf environments. Such periods of higher wave energy have been invoked in a number of areas where rapid rates of sea-level rise occurred in the early-mid Holocene, and discussed in relation both to large shelf systems, and the development of reefs and reef islands. However, spatial variations in the rate and timing of the post-glacial marine transgression, and variations in the depth of the substrates over which flooding occurred, means that the extent and longevity of any such window was probably highly variable between regions. Of interest in the context of near-future environmental change is the idea that such high energy windows may once again open up across reefs where the combined effects of environmental and anthropogenic disturbance interact to suppress reef growth potential (or even to drive reef erosion). Under such scenarios reefs may not be able to respond to even modest rises in sea level, thus allowing greater wave energy transfer across reef flats (see Sheppard et al., 2005). Where this occurs there will be obvious implications for lagoon and island sediment dynamics and shoreline stability.

## HOLOCENE REEFS: THICKNESS AND CHARACTERISTICS

Eberhard Gischler

Institut fuer Geowissenschaften, Frankfurt am Main, Germany

Continuous coral reef growth since the last glacial lowstand of sea level some 18 kyrs BP has been documented by drilling around the islands of Barbados (Fairbanks, 1989) and Tahiti (Bard et al., 1990). In the majority of cases investigated though, shelf reefs started to accrete not earlier than the Holocene (< 10 kyrs BP). Holocene reef thickness and accretion-rates exhibit large variation and can be as high as > 40 m and > 20 m/kyr, respectively (Dullo, 2005; Montaggioni, 2005). Scoffin (1992) has summarized how the synchronously operating processes of framework growth, bioerosion and breakage (reef destruction), encrustation, loose sediment accumulation, and cementation have resulted in late Quaternary reef accretion. A number of external factors such as antecedent topography, water temperature, nutrient concentrations, and exposure to waves and currents influence Holocene reef growth; however, sea level appears to exert major control. Neumann and Macintyre (1985) have elegantly categorized reef response to postglacial sea-level rise into keep-up, catch-up, and give-up reef anatomies. The keep-up type is characterized by branched acroporids and the catch-up type by branched and/or massive corals and shallowing upward facies. The give-up type shows

a deepening upward facies and the reef top is located in deeper water, in contrast to the keep-up and catch-up types where the reef top is more or less at sea level. Recently, Gischler (2008) and Hubbard (2009) have shown for the western Atlantic that Holocene reefs dominated by acroporids do not accrete faster as compared to massive coral reefs, even though acroporid corals exhibit growth-rates one magnitude higher as compared to massive corals. Also, reef accretion-rates did not correlate negatively with increase in paleo-water depth over an investigated range of 25 m. An explanation for these unexpected results might be that the effects of destructive processes in reefs decrease with depth. First, massive corals are more resistant and accrete with little disturbance in deeper water whereas shallow water acroporids are repeatedly leveled by cyclones. Second, current knowledge indicates that rates of bioerosion apparently decrease with increasing water depths. These findings also contribute to the question as to how much of a reef is represented by *in situ* framework and what percentage comprises transported detritus, a question that has been discussed for over a century by reef workers (e.g., Hubbard, 2009). It seems that in Holocene reefs – and possibly the same holds true for their fossil counterparts – detritus clearly exceeds autochthonous framework, and destructive processes are an integral component of reef accretion.

Huon Peninsula on the northeastern coast of Papua New Guinea is located at the overriding South Bismarck plate on the Australian plate and at 6°S. This tectonic and latitudinal setting allows the formation of spectacular uplifted coral terraces, which are regarded as one of the standards for eustatic sea level changes superposed on tectonic uplift (Chappell, 1974; Chappell and Shackleton, 1986). Terraced area ranges from ca. 2 to 15 km in width, separated by NW–SE trending Kalasa Fault from the Cromwell Range. However, Kalasa Fault partly truncates older terrace (Terrace XIV or XV), and branches into two on the southeastern end, cutting younger terraces.

The major coral terraces, I–XV in ascending order, record the high sea level of interglacial period and are constructional terraces underlain by coral limestone with transgressive facies, correlated with MIS 1 to 14 (Figure 1). Correlation of each transgressive terrace with MIS is supported by many U-series dates for Terrace VII and younger terraces (Chappell et al., 1996; Yokoyama et al., 2001; Cutler et al., 2003); however, older terraces are not well dated. Terrace VII (MIS 5e, ca. 124 ka) is especially continuous, and its height shows northward down tilting from ca. 400 to 50 m over ca. 70 km long coastline with the maximum uplift rate of 3.3 m/1,000 years. Preservation of original terrace surfaces is closely related to the amount of uplift and age of terraces. Holocene terrace of MIS 1, dated by radiocarbon method at many sites, also tilts from 25 to 5 m. Maximum height of preserved terrace XV is ca. 1,500 m. Formation of multiple terraces, including those for the relatively low sea level (MIS 5c, 5a, and 3), is resulted from such a high uplift, which has continued throughout the middle Quaternary.

The rapid uplift of the peninsula is associated with the repeated coseismic uplift, which is expressed by a series of small terraces cutting into the major terraces (Ota et al., 1993). Coseismic uplift has an order of 2–5 m in magnitude and ka order of repeat time, judging from the terrace height and ages. Coseismic uplift is recorded not only in the Holocene terrace but also in late Quaternary terraces (Ota and Chappell, 1996). This is very unique phenomenon caused by the good preservation of coral limestone resistant to physical weathering.

**Huon Peninsula, P.N.G., Figure 1** View of coral terraces at the Huon Peninsula. (Photo by Ota.)

Morphology of major terraces is characterized by the prominent barrier, lagoon, and barrier following streams. Presence of dense short gullies also characterizes the morphology of terrace risers. Doline is often seen on very extensive Terrace X and XI. Landslides and related debris flows, destructing or overlying the coral terraces, also provide characteristics features, many of which can be regarded by paleoearthquake (Ota et al., 1997).

## HYDRODYNAMICS OF CORAL REEF SYSTEMS

---

Clifford J. Hearn

Working Science Consultancies, St Petersburg, FL, USA

### Synonyms

Coral reef hydrodynamics; Currents on reefs; Water flow over coral reefs

### Definition

Hydrodynamics. The science of water flow and the forces that cause that flow.

### Hydrodynamics of coral reef systems

#### Water flow in coral reef systems

Coral reef systems are spatially inhomogeneous and consist of an amalgam of sub-systems, which have different benthos and widely varying geomorphology. These include the reef, or reefs, one or more lagoons, and regions of the neighboring ocean that are affected by the reefs. All

of these sub-systems are connected hydrodynamically by processes on the reef and these processes are the focus of the present article. Much of what happens on the reef, in terms of hydrodynamics, is controlled by the topographic complexity of the reef and is also affected by the surrounding environment of the reef system. Our attention is primarily directed towards shallow reefs and these may be either sub-tidal, or inter-tidal. Reefs may have varying types of benthos (coral, algae and sand) and are zoned in a way that affects bottom friction and many other aspects of their hydrodynamics. A recent survey of coral reef hydrodynamics is given by Monismith (2007).

Coral reef hydrodynamics differs in many important respects from the hydrodynamics of other coastal systems and these differences will be discussed here. The science of water flow over reefs is the cornerstone of much of our understanding of the ecology and biogeochemical dynamics of reefs. Its effects are multifarious and occur at many space and time scales. Coral reefs efficiently dissipate wave energy and constitute some of the best submerged breakwaters in the natural world (von Arx, 1948). This creates low-energy lagoons, which are fed with water from the reef (Hench et al., 2008) and also have their own patterns of water circulation (“entry lagoons”; “entry lagoon circulation”). Reef hydrodynamics can be greatly affected by conditions in the lagoons, and the outside ocean, and there are processes of continual recirculation of water that are augmented by astronomical tides.

Coral reefs have high biological productivity that is the marine equivalent of tropical rain forests (Hatcher, 1998). There are many similarities between the two systems: the structural complexity of reefs seems to have an important analog in tropical rain forests with the same degree of ecological complexity and biodiversity (Brown et al., 2002). At the heart of the processes which control such productivity are the dynamics, transport and recycling of nutrients and their dependence on the hydrodynamic processes at a variety of space and time scales (Hatcher, 1997). This includes all of the complex small scale vortices, and wave motions found on reefs, which are part of the turbulence field. Unlike most coastal systems, the spectrum of significant topographic complexity in reefs appears almost continuous from scales of hundreds of meters down to millimeters. There is a possible distinct change in the nature of this complexity at the scale of individual coral colonies and this is a physical scale that can be utilized in conceptual (and numerical) models of reef hydrodynamics.

Reef currents are produced by many types of environmental forcing of which the most important are breaking surface waves (“entry Waves and wave driven currents”), astronomical tides, and wind stress (Munk and Sargent, 1954; Kench, 1998). Other influences may also be present on some reefs such as the thermohaline processes (Monismith et al., 2006) and long period ocean oscillations; for the Great Barrier Reef see the excellent volume by Hopley et al. (2007). Of all these forcing processes, the most important is wave breaking and the

quintessential, and fundamental, problem of water flow in coral reefs involves waves breaking on a well-defined fore-reef (“entry Fore reef/reef front”) and flowing across the adjoining reef flat into a lagoon. The waves are usually ocean swell but can be wind waves (Kraines et al., 1998). This topography fits many reef systems and has been studied through conceptual and numerical models by Tait (1972); Symonds et al. (1995); and Hearn (1999) and recently reviewed by Monismith (2007). This “classical reef flow” problem is illustrated in Figure 1 and we shall discuss this prototype of all reef models in some detail.

There are two basic conceptual models of the physical structure of a coral reef. The first is the “solid reef model,” in which the reef is represented as a solid body (without reentrant surfaces in the vertical plane) to which are added “roughness elements.” This can alternatively be described as a “bathymetry model” since it can be totally described by a conventional bathymetry dataset with depth as a function of horizontal position. It is discussed in the following sections. The other type of model is the “porous reef model” mentioned later in this article. These conceptual models, which are used for analytical and numerical simulations, have been accompanied by so-called “physical models” built in many laboratories and also, at larger scale, as the coral reef mesocosm at the Biosphere 2 facility in Arizona (Atkinson et al., 2001). Such physical models provide much important hydrodynamic, chemical and biological data although there is limited guidance as to the correct physical, and ecological scaling parameters to be used in this model building.

In the solid reef model, the reef can, in principle, be treated by conventional coastal models (Peterson et al., 2006; Hearn, 2008). However, there are many aspects of flow over a reef that make it distinct from conventional coastal flow and these will be explored in this article.

### Friction on reefs

Part of the hydrodynamic uniqueness of coral reefs is that they are submerged natural structures that have the same efficacy as do solid barriers in dissipating ocean waves and creating calm lagoons. Their dissipation of waves is due to a resistance to water flow that can be treated as friction although it cannot be purely “skin friction” as in most coastal models. Instead, the friction comes primarily from “form drag” created by the irregularity and complexity of the structure. In solid reef models, the friction offered by reefs is created by the “roughness elements.” The simplest representation of such friction is a frictional drag coefficient. Approximate coefficients for bottom friction on reef flats were originally derived from field data relating incoming wave height and reef current (Hearn, 2008). A coefficient of friction for coral can also be obtained by measuring the current produced by a known head of water in a flume filled with living coral cut from a reef (Atkinson and Bilger, 1992). It is also possible to estimate friction coefficients from acoustic measurements of current either using profiles of current against height or by determining

**Hydrodynamics of Coral Reef Systems, Figure 1** The classical reef problem showing a typical reef with water elevation, current, relative dynamical forces and wave height.

the Reynolds stress. A review of some of this work, is given by Monismith (2007). These methods give values of quadratic friction coefficient of the order 0.01–0.1 compared with a typical value of 0.0025 for the skin friction from sand particles in coastal waters.

The use of a drag coefficient is rather limited for several reasons. Firstly, it follows from the theory of the logarithmic layer, that the coefficient will always increase as water depth decreases and so a comparison between values in the scientific literature necessarily requires a knowledge of that depth. Secondly, as discussed later in this article, the presence of waves causes the quadratic dependence of frictional stress to fail at low currents. Finally, the height of the “roughness elements” on reefs is necessarily an appreciable fraction of the height of the water column so that the simple models that lead to quadratic friction in coastal models are not completely applicable.

The part of the bottom of the water column around the roughness elements is called the “roughness layer” and fluid flow in this region is complex and dominated by inertia forces. We are only now starting to understand how to model water flow within the roughness layer and there are some similarities here with flow through canopies formed by submerged aquatic vegetation (Cornelisen and

Thomas, 2009). Experiments have been performed within flumes although the experimental reef structures built in the laboratory can lack important aspects of the real structural complexity found in nature.

Solid reef models, can accommodate some part of the processes within the roughness layer by a phenomenological modification of the Prandtl formulation of a vertical “mixing length.” For a roughness layer that is thin (compared to water depth), this mixing length method reproduces the familiar logarithmic layer profile of current against height within the water column. In such cases, measurement of this profile is a valuable method of finding the roughness lengths (Lacy et al., 2005). The value of the mixing length concept is that for a thick roughness layer, it can be modified so that, within the roughness layer, it has a polynomial dependence on height (Hearn, 2008).

### Spatial variability of roughness

#### Rough reef flat

The original solutions of the classic reef problem, illustrated in Figure 1, simply assumed that the drag coefficient, or roughness length, for the reef flat was the same as that on the fore-reef. This creates a balance of forces

on the fore-reef which is mainly between radiation stress and pressure gradient. The radiation stress is a representation of the force from breaking waves and the pressure gradient is due to a build up of water in the direction of those breaking waves called the “wave set up” (“entry Wave set up”). This results in the water level at the reef crest being higher than the outside ocean by as much as tens of centimeters. A similar effect can be seen on a seawall as waves break against it. This wave set up then causes water to flow across the reef flat, i.e., there is a pressure gradient across the reef flat which is balanced by the friction created by the current. Although smaller waves propagate across the reef flat, wave breaking there is very limited.

The zone of breaking waves is called the “surf zone” and is the most easily recognized region of a coral reef with its line of white breakers. The width of the surf zone is controlled by the height of incoming waves (usually swell) and the slope of the fore reef. The width varies greatly amongst the coral reefs of the world. Fore reefs with steep slope have narrow surf zones while gently sloping fore reefs have much wider surf zones. The current that is forced across the reef flat by the breaking waves originates in the region beyond the surf zone. It must then pass through the surf zone, onto the reef flat, and out to the lagoon where it returns back to the surrounding ocean. This essentially creates a large circulation cell, or a series of cells, the sizes of which are mainly controlled by the morphology of the lagoon. Circulation in the cells becomes very dispersive in the deeper ocean outside of the reef system. Water may also form closed gyres, or eddies, on the reef itself because the wave set up can vary laterally along the line of the reef crest. Water also flows laterally along the fore reef. The extent of this lateral flow is controlled by the lateral bathymetry and friction (which may be highly anisotropic).

The dynamical force which moves water onto the fore reef is a pressure gradient and this requires a “wave set

down” to be there, just in front of the surf zone which causes water to flow inward towards the surf zone where it must then ascend to the raised water level above the reef crest (Figure 1). It does this by using its own momentum or inertia. The region in front of the surf zone is therefore called the “acceleration zone.” Friction opposes this acceleration and so tends to increase the wave set down. This is illustrated in Figure 1. A major difference between the wave set up, produced by wave breaking, and the wave set down, due to friction, is that the latter increases with current. The wave set down therefore acts as a form of resistance which lowers the net water elevation at the crest when the current over the reef flat would otherwise become too high.

The model used in Figure 1 assumes that the lagoon is sufficiently deep to produce negligible surface elevation immediately behind the reef flat. In practice, most reefs have a “back reef” which is also shallow so that narrow lagoons behind fringing reefs such as Ningaloo (Hearn and Parker, 1988) may experience significant wave set up against the coast behind the lagoon.

### Smooth reef flat

Many reef flats can be quite smooth and this alters the reef hydrodynamics. If we reduce the roughness of the reef flat, we would expect the wave-driven current flow to increase since we would anticipate that the water level at the reef crest remains unchanged. This does occur provided that we do not decrease the roughness of the reef flat too much. As we further lower the roughness of the reef flat, the current increases sufficiently for the wave set down on the fore reef to effectively reduce the elevation at the crest so as to eventually limit the current. At sufficiently low roughness, the current across the reef flat tends towards a constant value and eventually becomes independent of that roughness. Figure 2 shows the current at the reef crest as a function of the coefficient of quadratic friction on the reef flat. This is derived from the simple one-dimensional

**Hydrodynamics of Coral Reef Systems, Figure 2** Current and energy dissipation at the reef crest as a function of the coefficient of quadratic friction on the reef flat.

model of flow across the reef, shown in [Figure 1](#), and based on a traditional quadratic friction law using a coefficient of friction on the fore reef of 0.1. This illustrates the importance of the spatial variability of roughness in a reef system across its many zones.

### Currents around reefs

Currents flow around reefs, as well as over, and through, the actual structure of the reef. As they do so, they create a series of coastal boundary layers near the reef and form island wakes. The structure of these wakes is controlled by the frictional Reynolds number (Hearn, 2008). The high friction, and limited water depth, associated with reefs lowers this Reynolds number and so causes island wakes around these structures (Tomczak, 1988). There are a series of studies of these wakes and the role of friction; for a good review see Wolanski (1994). Local artisan fisheries use their knowledge of these wakes, and whirlpools, around reefs, and their variation with the state of the moon, to navigate these waters and optimize catches (Johannes, 1981).

### Waves on reefs

#### Wave processes

The hydrodynamics of reef systems is closely connected with the processes of wave propagation and breaking on reefs. Waves are present on reef flats whenever there are incoming waves on the fore reef, and in the presence of breaking on the fore reef, the waves on the reef flat are just below the height at which they would break (for example, waves of height 0.8 m on a reef flat of depth 1 m). There are very considerable areas of research devoted to wave breaking and its dependence on the depth and shoaling of the reef and to the effect of the strong wave-current interaction on wave propagation, refraction and diffraction over reefs ("entry Wave refraction"). These processes have many interesting, and distinct, forms on reefs due to their unique structural and hydrodynamic properties.

#### Wave boundary layer

After breaking on the fore-reef, smaller waves (just below breaking height) continue to propagate over the reef flat and these effectively increase friction on the reef flat. In the solid reef model, this wave-current interaction occurs through the "wave boundary layer." The usual situation of waves propagating in the ocean is that their associated currents are not affected significantly by bottom friction. The reason is that the bottom stress is oscillatory and therefore has only the very limited time of half a wave-period to propagate up through the water column. Consequently, until waves enter very shallow water they do not feel significant influences of bottom friction; the vertical current is zero at the bottom of the water column (it is this constraint that changes the speed of propagation of waves in shallow water and produces refraction).

The limited time for propagation of the bottom stress into the water column restricts its influence to a bottom

layer (called the "wave boundary layer"). This layer is very thin in most coastal situations and so it just has the simple effect of increasing the coefficient of quadratic friction through the "wave-current" interaction. This situation is changed on reefs because the greater friction produces considerable turbulence from waves with much greater penetration into the water column. Consequently, the wave boundary layer on reefs can have a thickness comparable to the height of the water column and this effectively increases the roughness of the reef. The usual quadratic friction which we find in most coastal situations is a consequence of the current being responsible for both the generation of turbulence and bottom stress. Within the wave boundary layer, that turbulence is created by the waves. A consequence is that at low currents the bottom frictional stress on the reef can be linearly related to the current. This affects some of the basic hydrodynamics such as the relationship between incoming wave height and current (Hearn, 2008). The current-wave interaction always increases friction; it acts by preventing bottom stress decreasing quadratically at low currents. Parts of the wave boundary layer lie inside the troughs, or cavities, of the roughness elements. These are regions with only marginal penetration by the residual currents from the main part of the water column, and so (depending on their size) some of the cavities may be dominated by wave currents (Lowe et al., 2005a, b).

Wave breaking can produce currents in the order of 1 meter per sec on the reef flat although this is very dependent on the width of the reef flat and its friction. Currents in narrow lagoons behind wave-forced reefs can also be high and especially if there is a deeper trench, or "gully," running through the lagoon. Nearshore reefs parallel to shore ("entry Fringing reef circulation") have breaks in the reef line for water to exit the lagoon ("entry Boat channel"), and during heavy-swell conditions, currents can become extremely high and dangerous to swimmers and novice boaters. Currents on reefs advect and disperse suspended material, and particulate and our knowledge of currents and circulation is vital to an understanding of sediment dynamics and all mass transport ("entry sediment-dynamics").

### Tidal influences

Astronomical tides modulate all of the hydrodynamic processes in a reef system ("entry Tidal effects on coral reefs"). Within the solid reef model, shallow reefs may be completely dry at spring low tides so that the wave set up is confined to the face of the fore reef. In a porous reef model, water continues to have limited flow at these low tides. The overall effect of astronomical tides is to create a net inflow, or outflow (considering all boundaries of the reef system) that is controlled by the tidally varying water level in the reef system. Without the tide, this net flow will be essentially zero. These net tidal currents do depend on the size of the reef system but for small systems the net current is 90 degrees out of phase with the water

elevation. This is based on the water level inside the coral system remaining very close to that in the outside ocean and requires that the size of the system be much less than the distance traveled by a gravity wave in one tidal cycle (this is satisfied by most systems of size a few tens of kilometers).

In addition to these “out of phase” tidal currents, time series of water elevation and currents in a reef system, show currents that are “in phase” with the elevation (Kraines et al., 1998). If these are comparable in magnitude to the measured wave driven currents over the reef, it is likely that they are due to the modulation of those currents caused by the changing water level. If the periodic in-phase currents are positively directed over the reef on the rising tide, this means that increasing the water level increases the wave driven current. That may be due to the dilution of the effects of friction with increased height of the water column. Conversely, a decrease in current might be due to reduced wave breaking. This was studied in detail by Hearn (1999) and modeled by Hearn and Atkinson (2000) and is confirmed by measurements at Ningaloo Reef by Hearn and Parker (1988) (“entry Sea level changes and effects on reef growth”).

### Turbulent energy

Friction in reef systems produces turbulent kinetic energy in the water column. The rate of production depends on both friction and current. The simplest physical picture of the turbulence is a set of vortices, or eddies, with continuous

variation of size. It is believed that after kinetic energy enters the turbulence spectrum it cascades down through the vortices, with decreasing spatial scales, until it is dissipated at small scales by molecular viscosity (as heat). Production rates of turbulent energy vary spatially across the reef and are controlled by current strength and roughness (which includes the wave-current interaction). Some part of that energy production is transported to other parts of the reef, where it may dissipate, or leave the reef system, and the remainder is dissipated locally. This balance of turbulence generation by friction, transport of turbulence (by advection and diffusion) and its dissipation, is important to organisms for which biogeochemical and other processes are controlled by some aspect of turbulence. Many organisms, such as coral, have a major role in the development of the roughness elements which promote friction.

Figure 3 shows turbulent energy on the reef which was featured in Figure 1, for the case of a rough reef flat. The upper panel shows the turbulent energy distribution with, and without, the diffusion of turbulence. It shows that diffusion tends to broaden the peak in turbulence at the reef crest. The lower panel shows the rates of production of turbulence, dissipation and net transport which demonstrates that production and dissipation are balanced on spatial scales of meters, over most of the reef, although there is net transport away from the reef crest. A caveat is necessary here regarding the turbulence closure scheme of the model (Hearn, 2008), which is based on conventional coastal models and not yet verified for very rough surfaces. The measurement of production and dissipation in the field are technically

**Hydrodynamics of Coral Reef Systems, Figure 3** Turbulent energy on the reef (featured in Figure 1), for the case of a rough reef flat. The *upper panel* shows the turbulent energy distribution in the absence of diffusion (*broken line*) and with a high diffusion coefficient of  $100 \text{ m}^2 \text{ s}^{-1}$  (*full line*). The lower panel shows the rates of production of turbulence, dissipation and net transport.

**Hydrodynamics of Coral Reef Systems, Figure 4** Rate of turbulent energy production on reef flat (shown in Figure 1) without waves (broken line) and with maximum (just below breaking point) waves.

challenging tasks which were performed at Biosphere 2 in Arizona (Hearn, 2001b), Kaneohe in Hawaii and the Gulf of Aqaba in the Red Sea (Reidenbach et al., 2006). These measurements generally support the local balance of production and dissipation; the values for dissipation are based on the spectral use of the “inertial subrange” for turbulence (Hearn, 2010).

Turbulence production is increased by wave motion, especially at the bottom of the water column and Figure 4 illustrates the effects of maximum waves (just below breaking point) on turbulence production on the reef flat. The figure shows production with, and without, waves. In the absence of waves, the depth averaged current is  $0.37 \text{ ms}^{-1}$  (drag coefficient 0.09), giving a total production of  $5.0 \text{ mJ kg}^{-1}$ . With waves, the current drops to  $0.27 \text{ ms}^{-1}$  but production increases to  $8.1 \text{ mJ kg}^{-1}$ . We note that waves reduce the residual current but, through their effect on friction, increase turbulence production (and therefore dissipation).

Returning to Figure 2, the broken curve shows the rate of energy dissipation at the reef crest as a function of the coefficient of friction on the reef flat (with a fore reef of fixed roughness). Significantly, this shows there is an optimum value of the coefficient of friction on the reef flat that optimizes dissipation and therefore would provide maximum nutrient uptake rates within the dissipation-uptake law (Baird et al., 2004). Importantly, increasing roughness does not necessarily increase dissipation because the spatial variability of roughness is always an important control of hydrodynamic processes.

### Flushing times of reef systems

Flushing times, or residence times, of reef systems are controlled by advection and dispersion (“entry Residence

time”). Flushing processes resemble those in other coastal systems (Hearn, 2008) except that reefs have topographic complexity, high friction and turbulence, with strong wave induced advection (Kraines et al., 1998). Flushing times are defined for the whole reef system, or a sub-system (control volume). They are very dependent on the spatial scale of this subsystem. There are important issues as to the relative strengths of advection and diffusion (dispersion) which are dependent on spatial scale and have important consequences for the transport of many materials and the ecological dynamics of the reef.

Consider particles that are carried onto the reef from the surrounding ocean and have a volume concentration of  $C$  in the water column. If there is a sink for these particles on the reef, its strength can be represented by  $-\gamma C$  where  $\gamma$  has the dimensions of speed. Suppose  $h$  is the depth of the reef and  $u$  a typical current strength. In the absence of dispersion, the characteristic horizontal length,  $l$ , over which the sink affects the concentration  $C$  is  $uh/\gamma$ . Typical values of  $\gamma$ ,  $h$  and  $u$  are  $10^{-4} \text{ ms}^{-1}$ , 1 m and  $0.1\text{--}1 \text{ ms}^{-1}$ , respectively, so that  $l$  is of order 1–10 km. For dispersion

alone, the corresponding distance is  $\sqrt{hK_x^3/4\gamma}$  where  $K_x$  is the coefficient of horizontal dispersion, and so for a typical range of  $K_x = 1\text{--}10 \text{ m}^2 \text{ s}^{-1}$ ,  $l$  is of the order 50–1,500 m. This implies that reefs with currents  $u$  of the order  $1 \text{ ms}^{-1}$  are dominated by advection whereas dispersion can be more important to the transport process when  $u$  is of the order  $0.1 \text{ ms}^{-1}$ . We may also be interested in particles that are produced on the reef, and which have (ideally) zero concentration in the outside ocean. Particles drift downstream and diffuse laterally with a half-width of  $\sqrt{2xx_K}$  where  $x$  is distance from the point source and  $x_K$  is the characteristic distance  $K_x/u$ . Since  $x_K$  is typically 1–100 m so that over a typical reef width of 500 m, the plume will have a half width of 30–300 m depending on the dispersion coefficient and the advective speed.

These results may also be applied to subsystems of the reef using values of residual current and dispersion appropriate to those spatial scales. In some systems, tidal advection dominates flushing and this is important to the dynamics of many larvae (Hamner et al., 2007). A more rigorous approach to finding flushing times is to use the particle-age technique (Hearn, 2006).

### Richardson Plot

The detailed surface area of the individual elements of a reef structure (per unit horizontal planar area of the reef) is of major importance to biogeochemical processes and to the role of hydrodynamics in the ecology of the reef. The surface area, and height, of roughness elements also controls friction which is a prime process in reef hydrodynamics. Surface area is a controlling factor in the surface stress imposed on the reef by currents and waves, and so is important to the constant erosion that occurs on reefs (“entry Solution processes/erosion”) and especially to storm damage from extreme currents and waves (“entry Tropical cyclone/hurricane”).

One of the key theoretical tools used to study these structural aspects of reefs is the “Richardson plot” (Hearn, 2008). This is based on the length,  $S$ , of a chain which is composed of links of size  $s$ , and made to fit, as tightly as possible, over the surface of a reef between two points on the reef with a straight-line (not necessarily horizontal) separation  $s_0$ . The maximum link size that we could choose is evidently  $s_0$ . Experiments with chains are widely used on reefs (e.g., Purkis and Kohler, 2008) and we can also emulate these field experiments with numerical procedures if we have data on the three-dimensional structure of a reef. Numerically, we can also repeat the chain experiment using a net with individual mesh elements each having a surface area of  $s$ , fitted tightly over the reef, and compare the total area of the net,  $S$ , with the flat projection of that area  $s_0$ . These procedures give the linear (or areal) “rugosity”  $S/s_0$  from scale  $s_0$  to  $s$ . The decadal rugosity  $r_{10}$  refers to the case  $s_0/s = 10$ .

The Richardson plot is dependent on the position on the reef that we choose for our chain, or net, and will differ greatly between the various zones of the reef. So, we think of the rugosity as a strictly local measure. We can increase the length of the chain, or the total area of the net, until we cover the entire reef. As we increase the value of  $s_0$ , in this way, we span a larger part of the reef and so  $S(s)$  represents an average over an increasing length, or area, of the reef. In so doing, we do lose strictly local information through this averaging process.

Hydrodynamic models, whether conceptual, analytic, or numerical, use some sort of spatial network of cells which can have a variety of shapes which may not necessarily be the same for all cells. A bathymetry of the reef can be defined at the centers of these cells and this would be the basis of a solid reef model. We can, in principle, make a Richardson plot within each cell with  $s_0$  spanning that cell so that  $S(s)$  represents the cell’s “individual topography” within a larger scale “bathymetry” of resolution  $s_0$ .

The “dimensional roughness”  $\sigma$  from scale  $s_0$  to  $s$ , is defined as  $\log_{10}(r_{10})$ , or as the mean negative slope of  $\log(S)$  against  $\log(s)$ . It provides a “filling factor,”  $0 < \sigma < 1$  for the reef structure at scale  $s$  within the space defined by  $s_0$ . As an example, a line can be made to completely “fill” a two dimensional space. This is called a “Peano curve” after Giuseppe Peano (1858–1932). The length of a chain fitted over such a line doubles whenever we half the length of its individual links so that  $\sigma = 1$ . Values of  $\sigma$  at scales of 10–100 m for many coastal structures are of order 0.1–0.3, i.e.,  $r_{10} = 1.3$ –2.0. At scales from a few meters to kilometers, filling factors,  $\sigma$ , for reefs of at least 50% ( $r_{10} > 3.2$ ) are reported by Purkis and Kohler (2008) using Lidar data (“entry roughness”). Note that if  $\sigma$  approached unity at  $s = 10$  m, any “holes” in the structure would have a size less than 10 m. Increasing the filling factor increases the surface area and so assists the geochemical processes but does increase the friction and impede flow; it also increases stress, erosion and severity of storm damage.

Rugosity of natural surfaces tends to increase indefinitely as we reduce the spatial scale and this marks their

fundamental difference from geometric surfaces. For example, a geometric surface formed from a flat bottom covered with hemispheres fitted tightly together (so that it looks rather like the back of one of the preformed sheets, or boxes, used to pack hens’ eggs) is a geometric surface and has a limiting areal rugosity (at all spatial scales less than the diameters of the hemispheres) of  $1 + \pi \sim 4$  (relative to a flat plane). This limiting rugosity is otherwise independent of the diameter of the hemispheres. By contrast, natural surfaces do not reach a limiting rugosity at small scales although they may have distinct zones, or ranges, of spatial scales in which limits are effectively reached. In reality, our “egg box” example shows the same phenomenon since at small enough spatial scales we start to see an increase in surface area due to the small-scale structure of the actual material used in its construction. In the same way, most coastal systems are represented by a bathymetry, or topography, which represents the system down to scales of meters. There is then a separation of scales until we see variability at scales that represent sand ripples and sand grains. For these cases, the Richardson plot naturally divides into distinct regions on the  $s$  axis and the important hydrodynamic lengths correspond to values of  $s$  that separate these regions. For example, the roughness lengths used in most coastal systems is the scale at which sand ripples, or sand grains, start to change the Richardson plot. This separation of scales is important to the structure of hydrodynamic processes.

Topography complexity in reefs stretches from scales of 100’s of meters down to millimeters. One very important question is whether there are changes in the Richardson plot which allow some separation of scales. This is likely to occur at the size of individual coral colonies. This scale varies with position in the reef. The basic approach used by Hearn (2010) is to devise an unstructured spatial grid in which one colony occurs in each cell of the grid and cells do not span parts of colonies. Solid reef models incorporate high levels of rugosity at the sub-grid cell scales through increased values of the roughness length. Although simple intuitive estimates can be made of roughness lengths for experimental models, the best approach is to fit the Richardson plot inside a cell to a model of the roughness elements. This involves the form of  $S(s)$  averaged over a numerical cell ( $s_0$  = planar area of cell) with minimum  $s$  one to two orders of magnitude smaller than  $s_0$ . Critical to this fitting procedure is the spatial scales at which the roughness elements start to affect the Richardson plot. For, example, data for individual polyps have been obtained by magnetic resonance imaging from scales of hundreds of microns to centimeters (Zawada et al., 2006).

The Richardson plot for a linear chain can be used to probe the anisotropy of the reef structure. Anisotropy exists in “spur and grove” structures and is common on the windward side of reefs as part of the wave dissipation processes (“entry Spur and groove”). This is important to hydrodynamic processes and is accommodated either by using anisotropic friction or spatially resolving the structure within the bathymetry mesh.

**Hydrodynamics of Coral Reef Systems, Figure 5** Variation of current across reef flat shown in Figure 1 as a function of the height of roughness elements.

Both solid, and porous, reef models use roughness as part of the structural form of the model and require the model to incorporate some skin friction, i.e., conventional surface friction, and so retain a nominal separation of scales between form and skin friction. An example of this methodology is shown in Figure 5 which is based on the reef illustrated in Figure 1. Roughness elements have been built on the reef flat which has a depth 1 m and itself has quadratic skin friction. The model uses cells of a size of 1 m and within each cell there is a randomly chosen height for a roughness element with a maximum height that is varied in the figure from 0.1 to 700 mm. The figure shows that a reduction of current on the reef flat starts to occur for elements of a height of 10 mm and currents decrease rapidly once the height exceeds 100 mm which is 10% of the height of the water column. The model derives the balance of skin friction, inertia, i.e., momentum advection, and pressure gradient around the roughness elements which constitutes form drag. As with classical experiments in fluid dynamics, some skin friction helps to reduce form drag and prevent separation of the viscous boundary layer (Hearn, 2008). The dominance of friction due to roughness elements, over local skin drag, has been verified by Reidenbach et al. (2006) working in the Red Sea. Drag coefficients were measured via the bottom stress obtained from Acoustic Doppler Velocimeters. It was verified that covering the reef flat with plastic sheets did not significantly change these drag coefficients. So, while some skin drag is important, the friction that we find on reefs comes principally from the larger scale roughness.

### Porous reef models

The alternative to the solid reef, or bathymetric, picture of a reef is to treat the reef as a submerged porous system so that water can either pass over the reef or essentially percolate through the structure as in hydrological systems.

The porosity parameter  $p = 1 - \sigma$ , with range  $0 < p(s) < 1$ , effectively defines the “openness” of the reef structure at scale  $s$ . It is also evident that some fore reefs, and reef flats, have structures that contain flow paths that are essentially internal to the reef matrix and have direct surface expression only at the ends of the paths. Measurements of porous flow through reefs are limited. Possible techniques within bore holes have been successfully explored on the Great Barrier Reef by Oberdorfer and Buddemier (1986), on Davies Reef, and by Parnell (1986), on a fringing reef flat at Orpheus Island. They found flow through the reef to be fast although spatially inhomogeneous (Hopley et al., 2007).

Work on porous models is still at very early stages. A major part of the difficulty is measuring the three-dimensional structure of reefs. Optical (Brock et al., 2004) and multi-beam sonar measurements of water depth are providing adequate bathymetry data for solid reef models but do not probe reentrant surfaces of the structure. As such, they determine only “external porosity,” or “external roughness.” Furthermore, it is important to distinguish, and explore, individual colonies and reef structures (Kuffner et al., 2007). Construction of a porous reef model can be attempted from a knowledge of the variation of dimensional roughness  $\sigma(s)$  with scale  $s$ . Some limited experimental progress has been made (e.g., Lowe et al., 2008) with artificial reef communities built as very low canopies on the floor of flumes. These experiments are very similar to those conducted with artificial submerged aquatic vegetation (Nepf and Vivoni, 2000) but lack much of the vertical and topographic complexity, of natural systems, which are essential ingredients of their hydrodynamics.

Simple models of reef growth can be devised with “diffusion limited aggregation.” Simple codes are given by Hearn (2008) and much more detailed algorithms by Kaandorp and Kübler (2001). These are also valuable for experimental modeling of hydrodynamic processes such as the lattice Boltzmann method which is a class of “computational fluid dynamics” (CFD) techniques for modeling a wide variety of complex fluid flow problems with complex boundaries (Succi, 2001).

### Summary

The science of water flow in coral reef systems is a developing area of study and one that is important to much of our understanding of coral reefs. Data on physical processes on reefs is accumulating but still sparse. Much progress is being made in understanding, and measuring, the topographic complexity of reefs. Some of the consequences of that complexity are the nature of friction on reefs and the ways that it can be parameterized. More structural data is needed at spatial scales of meters to centimeters. One of the important properties of reefs that dominates much of reef hydrodynamics is the spatial variability of friction. Considerable progress is being made with models of reef hydrodynamics and our understanding of the roughness and wave boundary layers.

## IMPACTS OF SEDIMENT ON CORAL REEFS

Michael J. Risk<sup>1</sup>, Evan Edinger<sup>2</sup>

<sup>1</sup>Durham, ON, Canada

<sup>2</sup>Memorial University of Newfoundland, St. John's, NL, Canada

### Introduction

The relationship between reefs and sediments has been observed by humans certainly for centuries, and possibly for millennia. Columbus observed that his ships could take on fresh water by avoiding the fringing reefs of South America and sailing into the mouths of the Orinoco (Morison, 1974). Moreover, that keen observer Charles Darwin noted that “The deposition. . . of sediment, checks the growth of coral-reefs” (Darwin, 1842).

Since the earliest seafarers noted that they could approach reef-barred coastlines at river mouths, because no reefs occurred there, we have known that sedimentation kills reefs. In fact, throughout geologic history (including the present), sediment must be considered one of the great killers of reefs. Notwithstanding this, the field still lacks the definitive body of research that would allow management teams to set objective standards and to craft appropriate legislation.

### A geological perspective

A great deal of research has been conducted by geologists on coral reefs because of the hydrocarbon resources located within ancient reefs. The framework of these ancient reefs was produced by a wide variety of types of invertebrates, as well as corals with algae, brachiopods, crinoids, and mollusks included in the mix. Many ancient reefs are seen, whether in core or in outcrop, to be covered

by a shale unit, and the assumption has been made that the reefs were killed by sediment input. The immediate cause of the demise was not as important to the geologist as was the fact of the shale-capping unit, because that often transformed the porous reef unit into a hydrocarbon reservoir. Adams and Frenzel (1950), for example, attributed much of the alternating reef facies in the Permian Capitan Reef of West Texas to periodic death of individual reef units from sediment input. Kershaw (1998) describes the complex interplay between morphology and sediment input in ancient stromatoporoid reefs.

In the past few decades, however, further research has afforded more light on the possible/probable causes of reef demise in the fossil record. Hallock and Schlager (1986) suggested that the death of the entire reef tracts could be due to increased surface productivity, driven in turn by increases in nutrients. In the fossil record, increased nutrients can result from increased rainfall, changes in current patterns so as to increase upwelling, or changes in sea level. In today's oceans, of course, increased nutrients are almost invariably the result of human activity. Although reefs have faced sediment stress since their inception, there is evidence that the threat is increasing due to human activities (Fabricius, 2005). Globally, fluvial sediment delivery to the world's oceans is increasing as a result of deforestation and other land clearing for agriculture, although this increase is countered in many watersheds by sediment trapping behind dams (Syvitski et al., 2005).

Hallock and Schlager discuss the changes in reef structure and reef sediments caused by increasing nutrients, and suggest that this process could be linked to the demise of fossil and modern reefs. Their paper functions as a framework, against which various hypotheses for reef decline may be tested. This is also one of the few papers in the past two decades treating reefs as a whole that gives proper place to the critical role of bioerosion in the balance

between reef accretion and reef destruction. In fact, they state (p. 389) "Because rates of carbonate production and bioerosion are similar, even modest increases in nutrient availability can shift a reef community from net production to net erosion." Their treatment of the role of nutrients emphasizes light penetration, and its subsequent diminution by phytoplankton blooms that are driven by nutrient increases. With increasing input from runoff, they envisage a "halo" of nutrients that precede the (usually siliciclastic) sediment input that impacts reef biota, so that by the time the reef is buried by sediment it is already dead or dying.

It is this unholy duo of reef stress, the inextricable linking of sediment input and nutrient increase, that has made the field such a difficult area of research.

That is not to deny the profound, fundamental effect sediment supply and type has on reef development. Roberts and Murray (1983) describe extensive carbonate bank development off the coastline of Nicaragua, an area, which receives copious amounts of rainfall and terrigenous sediment: 3 times more fresh water and 15 times more sediment are introduced per unit length of coastline than on the east coast of the USA. There is an inner smooth-bottomed ramp of siliciclastic sediments parallel to the coast: transition to *Halimeda*-rich bottom sediments is abrupt, and takes place approximately 20 km off the coast. In general, the frequency and proliferation of reefs increase away from the turbid coastal boundary layer and toward the cooler and saltier water that upwells at the shelf margin. But again, nutrients cannot be excluded from the picture. The lack of reefs along the Nicaraguan Rise is at least partly attributed to nutrient increase driven by topographic upwelling (Hallock, 2001).

Acevedo et al. (1989), working in Puerto Rico, reported that increasing coastal development near Ponce, on the south coast, had caused an increase in turbidity, manifesting itself as a plume of sediment-laden water that drifted to the west over a series of reefs. Their survey work showed that total coral cover and diversity was reduced near the sediment source. The surviving corals were sediment-resistant. The effects of the sediment included partial or total burial of corals, bleaching, and colonization of the surface by filamentous cyanobacteria. Reduced light levels resulted in domination of the remaining coral community by species normally found at greater depths—findings similar to those of Cortes and Risk (1985).

Descriptions from the Indo-Pacific of the effects of sediments on modern reefs are equally abundant, and equally well established (Marshall and Orr, 1931). There are descriptions of the effects of mining (Chansang et al., 1981), as well as outlines of the general impact of sediments from activities such as dredging and increased runoff (Endean, 1976; Johannes, 1975; Fabricius, 2005).

## Demonstrated effects of sediments on reefs

### Decrease in coral growth rates

There have been many studies linking decreases in coral growth rates with increased sediment stress, usually from

disturbances such as dredging and deforestation. Bak (1978) found calcification rates decreased by 33%; Dodge and Brass (1984) reported that corals from sites on reefs of St. Croix, US Virgin Islands that had been disturbed by dredging had lower extension and calcification rates than corals from unaffected reefs. Dodge and Vaisnys (1977) found that the growth rate of *Montastrea annularis* in Jamaica decreased as a function of sediment resuspension rates; interestingly, Cortes and Risk (1985) studied the same species in Costa Rica. Their reported resuspension rates were much higher than Dodge and Vaisnys (1977), but produced the same linear relationship. This suggests that coral species have the same responses to sedimentation in different locations.

Tomascik and Sander (1985) investigated the effects of water quality on *M. annularis* growth rates off Barbados over a gradient of increasing eutrophication (primary sewage, industrial effluent). They found that mean concentration of suspended particulate matter ( $\text{mg l}^{-1}$ ) was the strongest single estimator of growth rates, with the most rapid coral growth occurring at the site farthest from the primary pollution source.

On the other hand, there is differential species response to similar sediment loadings. Large colonies, and/or species with thick tissues, are often relatively resistant, whereas smaller colonies, and species with thin tissue layers may be greatly affected (Rogers, 1990; Stafford-Smith, 1993; Fabricius, 2005).

Care must be taken when interpreting growth rates reported in the literature, especially in older articles. Coral "growth rate" is not simply linear extension, but should be seen as calcification rate, the rate at which corals can make skeleton. This is the product of both extension rate and density, and it must be noted here that Brown et al. (1990), saw no detectable decrease in coral calcification as a result of dredging.

Because sediment input and nutrient concentration frequently (usually) covary, corals are affected by two conflicting factors: increased sediment input slows growth, while at the same time individual corals may grow faster under conditions of elevated nutrients. These same corals will then face intense competition from algae and non-calcified benthos, and bioerosion soon outstrips accretion rates. This bifold effect of nutrients on coral reefs has been called the "Janus Effect," after the two-faced god of Roman mythology so familiar to theatre-goers (Edinger and Risk, 1994).

Edinger et al. (2000b), working in Indonesia, were able to tease apart the conflicting influences of nutrients and sediment stress. *Porites lobata* coral extension rates increased from oligotrophic to mesotrophic conditions, then decreased again toward eutrophic and hypertrophic conditions as turbidity from sediments and phytoplankton reduced light penetration to corals (Figure 1). High variance in extension rates was observed on polluted Java Sea reefs. They found that extension rates on polluted nearshore reefs were high, and could not be statistically distinguished from extension rates from cleaner offshore reefs, not

**Impacts of Sediment on Coral Reefs, Figure 1** Diagram of the effects of increasing sediment and nutrient input from land, on the carbonate balance of reefs. Modified from Edinger et al. (2000b).

affected by sediments. Among reefs impacted by combined sedimentation and eutrophication, only one of five reefs showed a decrease in average coral linear extension rates through time. Coral skeletal density in nearshore, polluted environments, however, was significantly lower. Low density, high-extension skeletal growth may be a sclerochronological signal of combined sedimentation and eutrophication effects on corals. One of the key conclusions of Edinger et al. (2000b) was that coral growth rates may be a poor indicator of whole-reef health, given the conflicting effects of covarying sediments and nutrients.

#### Partial or total mortality

Death of all or a part of coral colonies has been associated with purported sediment stress. Marszalek (1981) reported partial mortality, accompanied by copious mucus secretion by the corals. Many corals secrete mucus when stressed by sediments; evidently as a defense, the mucus is shed off the colony, carrying with it the trapped sediment (Figure 2). In a series of papers, Bak and coauthors (Bak, 1978, 1983; Bak and Steward-van Es, 1980) outlined a series of experiments and observations linking partial coral mortality to external stress. In their work in Thailand on the impacts of dredging, Brown et al. (1990) described partial coral mortality, accompanied by mucus secretions. Nugues and Roberts (2003) described partial mortality on corals in St. Lucia, and suggested that a measure of partial mortality may be used as an indicator of sediment stress.

#### Decrease in metabolic rate

Rogers (1979) shaded a portion of San Cristobal reef (Puerto Rico) to simulate the shading effects of turbidity and found decreased net productivity by the coral community. Dallmeyer et al. (1982) found a decrease in net production by *M. annularis* colonies exposed to particulate

**Impacts of Sediment on Coral Reefs, Figure 2** Fine carbonate sediment bound into a mucus sheet on a colony of *Porites*, Zanzibar, East Africa. This coral also exhibits the multilobate morphology believed to result from sediment stress.

peat during daytime experiments. At night, colonies exhibited increased respiration and active clearing behavior. Telesnicki and Goldberg (1995) found that high turbidity increased mucus production, and depressed P:R ratio to below 1.0.

More recently, Philipp and Fabricius (2003) assessed the effect of sediment stress by using PAM fluorometry on field and laboratory experiments on the Great Barrier Reef. Within the ranges measured, sedimentation stress of colonies exposed to large amounts of sediment for short periods of time was similar to that exposed to low amounts of sediments for prolonged periods of time. Colonies recovered from short-term sedimentation stress within <36 h, whereas long-term exposure, or high levels of sedimentation, killed exposed colony parts.

#### Changes in coral population structure

Several authors have observed that one of the effects of sediment stress appears to be a replacement of shallow-water species by species characteristic of, or adapted to, deeper reef zones (Cortes and Risk, 1985; Acevedo and Morelock, 1988). Rogers (1990) suggested that heavy sediment stress should result in an upward shift in depth zonation.

It has also been suggested that, as a consequence of reduced recruitment on heavily sedimented reefs, the population structure of the surviving coral will shift toward a preponderance of large, old colonies. At Cahuita, Costa Rica, Cortes and Risk (1984) found a correlation of heavy river discharge with lower diversity, lower cover, lower growth rates, and generally larger coral colonies. Maragos (1974) also found larger colonies in the turbid lagoon than in the clear lagoon at Fanning Island.

#### Changes in coral morphology

Colonies of *Agaricia agaricites* and *M. annularis* exhibited changes in orientation and morphology, which

appear to reflect adaptations to sediment stress (Bak and Elgershuizen, 1976). Logan (1988) suggested that the frequently observed orientation of the large calyx in *Scolymia cubensis* at a steep angle from the horizontal may be an adaptation, which facilitates sediment removal. Under high sedimentation conditions, massive coral colonies often take on a multilobate morphology, which allows the coral colony to continue extending upward in some portions, while other portions of the colony grow slowly or die altogether.

### Reduced species richness and diversity

A reduction in the number of species of coral, coral cover, and the diversity of the coral assemblage seems to be virtually universal results of sediment stress. Such results have been reported by many authors, and only a few examples can be given here: Caribbean-Costa Rica, Cortes and Risk (1985); Puerto Rico, Acevedo and Morelock (1988); Virgin Islands, Rogers (1983); Bermuda, Dryer and Logan (1978); Indian Ocean-Kenya, Obura et al. (2000); Arabian Gulf, Sheppard et al. (2000); Madagascar, Gabri   et al. (2000).

It is perhaps in Southeast Asia, where major rivers, abundant reefs, impoverished coastal populations, and rampant development all converge, that perhaps the most depressing examples of sediment-driven reef degradation may be found: Philippines, Hodgson and Dixon (1988); Singapore, Chou (1997), Dikou and van Woesik (2006); Thailand, Chansang et al. (1981).

Indonesia has more coral reefs than any other nation, and also some of the most badly damaged reefs. Edinger et al. (1998) described the trajectories of decline of reefs from several areas near Java, Sulawesi, and Ambon (Moluccas), and outline the impacts on diversity from sediments, nutrients, and direct human impacts such as anchor damage. Combined sedimentation and eutrophication caused greater change in species composition than either factor alone, or than mechanically induced stresses such as blast fishing or anchor damage (Edinger et al., 2000a). Science writing is supposed to be dry and objective, yet it is hard to read the description, by Tomascik et al. (1994), of the decline of the reefs in Jakarta Bay without feeling it is a modern tragedy. They quote Umbgrove (1939), writing about the reefs of Nyamuk Besar ("Big Mosquito" in Bahasa Indonesia; Leiden, to the Dutch residents): "The unrivaled splendor and wealth of forms and the delicate tints of the coral structures, the brilliant colors of fishes, clams, sea anemones, worms, crabs, star fishes and the whole rest of the reef animals are so attractive and interesting that it seems impossible to give an adequate description of such a profusion of serene and fascinating beauty."

Those reefs have now disappeared. Tomascik et al. describe the disappearance of entire reef tracts in Jakarta Bay and the adjacent ocean waters, driven by the onslaught of sediments and nutrients from the city. They go on to say (p. 309): "Jakarta Bay is not an isolated case of reef degradation, which is now a worldwide phenomenon. . . monitoring. . . will not prevent the demise of coastal

reef ecosystems, but ecologically sound management practices and coastal development based on sustainable principles just might."

### Reduced larval settlement

As might be expected, the early stages of coral development, the processes of larval settlement and development, are strongly affected by sediment in the water column. Tomascik and Sander (1987) suggested that lower light levels may inhibit development of coral larvae by reducing the amount of energy available to maturing ova or embryos. They found reduced numbers of larvae from colonies of *P. porites* growing on reefs polluted by nutrients and suspended particulate matter with increasing levels of sedimentation and eutrophication.

Sedimentation mortality thresholds for coral recruits are an order of magnitude lower than those for larger colonies (Fabricius et al., 2003). Few coral larvae settle on sediment-covered surfaces, and survival on such surfaces is minimal. At moderate to high rates of sedimentation, successful larval settlement is restricted to downward-facing surfaces where growth and survival are negatively affected by low light.

In short, there is a long list of perceived impacts on corals that have been attributed to the effects of sediments. At present, however, these are impacts in search of mechanisms. The field requires more research on the specific modes of action, by which sediment stress achieves the observed results.

### Mode of action of sediments

There are basically three avenues that have been suggested and by which sediments can stress corals:

#### Decreasing the available light

The logic behind this hypothesis is that decreased light levels would reduce the amount of energy translocated from the zooxanthellae to the host, resulting in slower growth. Rogers (1979) shaded corals in the field, and observed partial mortality. Several other authors have also observed the decrease in coral vigor, which may be produced by decreased light levels (Telesnicki and Goldberg, 1995; Anthony and Hoegh-Guldberg, 2004). Furthermore, fine-grained siliciclastic sediments reduce light penetration more than equivalent concentrations of carbonate sediments (Te, 1997).

#### Metabolic drain

When sediments land on corals, the corals usually try to clean themselves by ciliary action, tentacle waving, or mucus sheet secretion. These responses on the part of the coral suggest that there is a metabolic cost to the corals involved in sediment deposition (Telesnicki and Goldberg, 1995). Corals have a variety of mechanisms for coping with sediments including use of their tentacles and cilia, stomodeal distension through uptake of water, and entanglement of particles in mucus, which later sloughs

off the colony surface (Hubbard and Pocock, 1972). Corals exhibit both active and passive removal of sediment particles (Lasker, 1980). In coral colonies, sedimentation stress increases linearly with the duration and amount of sedimentation: for example, a certain amount of sediment deposited on the coral for one time unit exerts the same measurable photophysiological stress as twice the amount deposited for half the time (Philipp and Fabricius, 2003).

### Microbially mediated decline

This is a relatively recent concept, that links together the co-occurrence of sediment input, dissolved organic matter (DOM), and nutrient increases, such as would accompany river discharge (either normal, or augmented by human activities such as deforestation) with increased bacterial activity. The augmented microbial processes would then increase the virulence of disease, alter the dynamics of fine sediments, and kill corals directly.

Much of the earlier work on sediments and corals paid little attention to the mineralogy and the size distribution of the sediments. This bears further investigation, because mineralogy plays an important role in the potential delivery of toxic and/or deleterious substances to the corals. For example, the phyllosilicate lattices of clay minerals, which will be delivered from the weathering of silicate rocks, are capable of storing (and later releasing) enormous amounts of dissolved substances, trace metals, and contaminants. Because of the edge charges on the unit cells, clay minerals can also form aggregates, or flocs; this tendency is enhanced in the presence of organic matter. Fine-grained carbonate sediments (micrites) lack this storage and agglomeration capabilities; hence, siliciclastic sediments can be predicted as posing greater threats to corals than the same amount of carbonate sediment (cf. Te, 1997).

Impacts of sediments on corals are strongly influenced by the type of sediment. Tissue damage under a layer of sediment increases with increasing organic content and bacterial activity, and with decreasing grain sizes (Hodgson, 1990; Weber et al., 2006). Low levels of sedimentation, when combined with “marine snow,” killed newly settled coral recruits. The same amount of sediment without the addition of marine snow does not reduce their short-term survival (Fabricius et al., 2003). Kline et al. (2006) have shown that increased DOM can cause elevated bacterial activity, leading directly to coral death.

As an example of the sort of research that is needed in this field, Weber et al. (2006) studied the effects on corals of sediments differing in grain size, organic content, and geochemistry. They found that different sediments exerted greatly contrasting levels of stress in the corals, and that grain size and organic and nutrient-related sediment properties are key factors determining sedimentation stress in corals after short-term exposure. Photophysiological stress was measurable after 36 h of exposure to most of the silt-sized sediments, and coral recovery was incomplete after 48–96 h recovery time. In contrast, sandy sediment types caused no measurable stress at the same

concentration for the same exposure time. Stress levels were strongly related to the content of organic matter and nutrients in the sediments. Anoxia developed on the sediment surfaces of the nutrient-rich silts, which had become slimy and smelled of hydrogen sulfide, suggesting increased bacterial activity. Their findings may be summarized as follows: silt-sized and nutrient-rich sediments can stress corals after short exposure, while sandy sediments or nutrient-poor silts have little effect.

### Summary of impacts

In short, the effect of sediments on corals and coral reefs may involve the effect of nutrients and bacteria carried by the sediment plume, as much as the sediments themselves. Although, both shading and particle loading are coral stressors, it would appear that, at least in some cases, shading suppresses coral growth to a greater extent than particle loading per se (Anthony, 1999).

There have been several experimental investigations of the sediment rejecting capabilities of corals (Hubbard and Pocock, 1972; Bak and Elgershuizen, 1976). In addition, in both the Caribbean and the Indo-Pacific, there have been attempts to establish a hierarchy of rejection capabilities among species of corals (Rogers, 1990; Stafford-Smith and Ormond, 1992). Some of the earlier attempts to assess sediment stress have used pulsed loadings of mostly coarse sediment (sand), which bears little relevance to the typical sediment stress applied to corals unremitting muddy water. Some recent research has, however, begun to shed more light on this complex problem (Anthony, 1999; Riegl, 1995). Reefs can, of course, occur in turbid settings. These tend to be thin accumulations, of low diversity, but nonetheless they survive (Perry and Larcombe, 2003). From a management perspective, the important factor is a *change* in water quality.

### Status of research

There is still a great need for research that would establish the limits of acceptable sediment input to any given reef. There may be an indication that Caribbean reefs, at least, cannot for long survive continued levels of SPM (Suspended Particulate Matter) in the surrounding water greater than 10 mg/L (Cortes and Risk, 1985; Abdel-Salam and Porter, 1988), but the certainty of this level is far from established, and legislation based on it is equally far off. In addition, there is a suggestion that some Indo-Pacific reefs flourish at SPM levels much higher, in some cases by shifting their metabolism toward more heterotrophy in murky waters (Anthony, 2000).

There are a number of reasons why research in this field has not progressed as rapidly as perhaps it should. First of all, perhaps the most frustrating, is the inability of workers in the field to agree on common methodology. Sediment deposition rates are usually estimated using sediment traps, but almost every published study uses a different design (trap height, diameter, emplacement above the bottom), and virtually none of them cites Gardner's work on

the proper design of a sediment trap (Gardner, 1980a, b). This is important, because traps with too large a ratio of opening to height will undertrap, whereas those that are taller, with smaller openings, will overtrap. Only traps with the proper design, beginning with a height: diameter ratio of about 3 will produce results that may be compared among sites and locations. In addition, sediment should be removed from the traps every few days, poisoned, and archived. Much of the information in the literature derived from sediment traps, in short, is either undependable or of use only in a limited geographic area. In addition, the material caught in a sediment trap represents both resuspended and net sediment, and these need to be differentiated if a complete picture is to be developed.

There has also been wide divergence in the methods used to measure sediment in the water column, SPM. Engineers and water quality workers have developed instruments, "nephelometers" that basically measure the attenuation of light through a water column as a measure of turbidity. The material in the water, however, may be a richly confusing mixture of alive and dead organic matter, dissolved substances, and sediments of varying grain sizes, colors, and mineralogy. Consequently, a stable synthetic material called "Formazin" with uniform particle size is often used as a standard for calibration and reproducibility. The results are Formazin Turbidity Units, or FTU. In the USA, the EPA has specified a white-light source and certain aspects of the instrument, to obtain Nephelometer Turbidity Units, or NTU.

The main attraction of these measurement techniques is that they are quick and easy, but, like many quick and easy methods, they often come with inherent errors. Because the type of sediment and the proportions of plankton and other organic matter can vary so widely, best practice is to calibrate the nephelometer against actual SPM values at each site and then, of course, the values so attained may not readily be transferred to other sites.

The other method used to determine suspended particulate matter is direct measurement: a known volume of water is filtered through a pre-weighed fine filter (generally 0.45  $\mu$ ), and the filter is dried and weighed (the method is described in Cortes and Risk, 1985). This process takes more time, but provides precise estimates. Perhaps equally important, the filters may be saved for later analysis of mineralogy, micropaleontology, and trace elements.

FTU and NTU should not be used in reef research. The quality of the data so produced is inadequate for research purposes, although the ease of acquiring such data may be attractive. Although NTU have been used by, for example, USEAP to set water quality guidelines, the high SPM values that characterize many reef sites, and the critical importance of being able to identify sediment provenance, mitigates against the instrumental methods in use.

Discussion of sediments in the literature has also suffered from some imprecision. Resuspension rates are not the same as sedimentation rates. From the point of view of the coral, an area with constant resuspension of bottom sediments is just as stressful as net deposition of the same

amount of sediment, yet the two situations represent very different settings. Corals react differently to fine versus coarse sediments – in addition, the textural and chemical properties of sediment are a function, at least in part, of the mineralogy.

Ideally, then, any study of sediment stress on a reef should therefore provide information on sediment deposition rates, resuspension rates, and SPM values, as well as data as to grain-size distribution and mineralogy. The number of published articles satisfying these requirements is disappointingly small.

The reasons for this may lie in the fact that much of the literature on the effects of sediment leaves much to be desired. Because coral reefs are a geobiological construct, their study – even more so than other ecosystems – requires a fundamentally interdisciplinary approach. The need for this has been a subject of comment many times (e.g., Risk, 1999), but the tendency still is to a one-dimensional approach.

Not only has some of the previous work on sediment stress been less than ideal, there has been delay in adopting some useful techniques. That corals incorporate sediment into their skeletons has been known for decades (Barnard et al., 1974). Cortes and Risk (1985) used this phenomenon to assess sediment input by decalcifying coral samples and estimating the insoluble residue. True, it only is effective where the incoming sediment is siliciclastic; the high variance encountered in Budd et al. (1993) arise from mixing samples, from sites with predominantly siliciclastic sediments as background input with samples from carbonate terrain. Davies (1992) showed that corals incorporate sediments through micro-lesions in the tissue, which in turn may be caused by sediment stress. Where others have used this technique to assess sediment stress, it has proven to be useful. Macintyre et al. (1994) traced the decline of a *Porites*-dominated reef in Golfo Dulce, Costa Rica, by analyzing the mineralogy of sediments trapped in coral colonies. David (2003) estimated input of heavy metals from mine tailings in the Philippines, and Edinger et al. (2008) traced the impact of gold mining on corals of Sulawesi, Indonesia. Brown et al. (1990) reported the incorporation of iron into coral skeletons in Thailand. Recently, Risk et al. (2009) have suggested that it may be possible to tease out the mixed influences of sediment and nutrients by plotting trapped sediment in coral samples (insoluble residue) against  $\delta^{15}\text{N}$  of the coral tissue; this is an area that needs more work.

The corals themselves also may not cooperate with studies designed to show linear responses to sediment stress. In nature, incoming sediment usually will contain additional nutrients and plankton, so it represents a potential food source as well as a potential stressor. Many coral species are very plastic in their feeding behavior, and have been shown, for example, to shift to a more heterotrophic feeding mode when faced with increased sediment. Anthony (2000) has shown this experimentally, and Risk et al. (1994) have shown that past metabolic shifts are recorded in the isotopic signatures in the skeletons. Similarly, Risk

et al. (1994) and Sammarco and Risk (1999), using stable isotopic tracers of metabolic activity, have shown that near-shore corals of at least some species can obtain much of their nutrition from terrestrial sources. Analysis of  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  of *P. lobata* coral tissue of Indo-Pacific reefs subject to combined sedimentation and eutrophication showed the influence of both enhanced algal photosynthesis, fueled by increased inorganic nutrient availability, and heterotrophy, fueled by increased dissolved or particulate organic matter availability. The relative enhancement of these different processes, in differing proportions, depends on the relative influences of turbidity, organic matter loading, and inorganic nutrient loading.

Recent research on the fringing reef of Molokai, Hawai'i by the USGS has set the bar for sediment research in coral environments. As a selection from this large body of work, Bothner et al. (2006) employed very sophisticated sediment traps, and were able to conclude that sediment input to the reef was episodic, driven by storms. What is more, sediment traps were found not to be good indicators of net sediment accumulation. Presto et al. (2006) studied the temporal and spatial variability of flow in suspended sediments on the reef flat, and found that most of the sediment was transported alongshore. Regions where sediment moved offshore were regions of low coral cover. Calhoun and Field (2008) studied the composition of grain types from the beaches and reef environments, and were able to deduce transport directions. And finally, much of this research is summarized in the beautifully illustrated USGS report (Field et al., 2008).

### Guidelines – how much sedimentation is too much?

In short, development of an integrated set of guidelines for sediment resistance of reefs has been hampered by lack of agreement on methodology, lack of precision when dealing with the sediments themselves, the confounded effects of increased sediment input and increased nutrients, and the plasticity of coral behavior.

It is highly unlikely that there can ever be one set of regulations, or guidelines, developed for all reefs that could control impacts of sediment (cf. Pastorok and Bilyard, 1985), nor is a global set of water quality guidelines necessarily desirable. It would seem that most Caribbean reefs have difficulty surviving SPM loads that are consistently in excess of 10 mg/L, and indeed it would seem appropriate to incorporate that level into regulatory guidelines. Reefs in other locales, for example, the northern Great Barrier Reef, will have adapted and evolved to survive very different conditions (Hopley et al., 1990, 2007). Corals near the mouth of the Daintree River flourish under conditions that would slay a Caribbean reef (cf. Perry and Larcombe, 2003). Within each region, corals have adapted to long-term regional variation in normal sedimentation rates and patterns. High-ambient sedimentation levels are not inherently stressful; rather, it is the change in the rates of sedimentation that causes stress for coral reefs (Fabricius, 2005; Hopley et al., 2007).

Even recognizing that change in sedimentation rate, rather than absolute sedimentation rate, is crucial for coral reefs (cf. Dikou and van Woesik, 2006), it is unlikely that a single critical value for percentage increase in sedimentation can be identified for all reefs. Sedimentation in many environments is highly episodic, and corals living in areas of high ambient sedimentation can probably tolerate a higher variance in sedimentation rate than those living in clear-water, low-sedimentation settings. It is highly likely that separate guidelines will have to be developed for each reef province, and we are a very long way from being able to produce those guidelines.

### Sclerochronology: the two-edged sword

Sclerochronology is the study of past environmental conditions by way of the study of the records in skeletons; corals and bivalves are the most commonly used. By “two-edged sword” here it is meant that, in many cases, corals are capable of recording the timing and extent of the very stresses that are killing them.

Coral skeletons record the environmental conditions under which the coral has grown, and in particular can provide an annually resolved record of how those conditions have changed through the life of the coral. Variables responding to sediment that can be recorded in coral skeletons include skeletal density, extension and calcification rates, quantity and mineralogy of insoluble residue, stable isotopes of C and O, and trace element geochemistry. Insoluble residue mineralogy and trace element geochemistry are particularly useful for studying the effects of sedimentation on reefs, especially determining the source of sediments. Trace element studies in coral skeletons have been particularly useful in recording sedimentation from natural terrestrial runoff (often enhanced by land clearing for agriculture or forestry), urban runoff including sewage pollution, and mine tailings. The discussion below focuses on trace element analyses of coral skeletons to reflect quantity and type of sedimentation. Trace elements differ in the extent to which they are incorporated into coral skeletons as a function of their valence state and atomic radius. Cations with valence similar to Calcium, such as Strontium and the Lanthanides are most readily incorporated into the aragonite crystal lattice, explaining why Sr/Ca ratios can be consistently recorded in coral skeletons at mmol/mol levels (see Gagan et al., 2000 for review). Ratios of Mg/Ca, Sr/Ca, and U/Ca respond to sea-surface temperature consistently, but with varying sensitivity (Fallon et al., 2003). These elements are useful in sediment studies for chronological control (in seasonal settings) and for records of changing oceanographic conditions at seasonal to decadal time-scales. Trace elements offer advantages over  $\delta^{18}\text{O}$  and fluorescent bands in responding to sea-surface temperature independent of salinity or fluvial discharge, but are most powerful as recorders of climate variation when combined with  $\delta^{18}\text{O}$  (Gagan et al., 2000). Other trace elements reflect natural and anthropogenic sedimentation directly (see below).

Trace elements in coral skeletons can be measured by drilling out samples of coral skeleton, followed by wet chemical analysis using atomic absorption spectrometry (AAS; Khaled et al., 2003), inductively coupled plasma mass spectrometry (ICP-MS; e.g., Fleitmann et al., 2007), or inductively coupled plasma atomic emission spectrometry (ICP-AES; Bastidas and Garcia, 1997; David, 2003). Of these, the standard method recommended by USGS is ICP-AES (see Bastidas and Garcia, 1997; David, 2003). Recent developments in laser-ablation mass spectrometry (LAM-ICPMS) and secondary ion mass spectrometry (SIMS) allow high-resolution sampling of trace elements in coral skeletons without wet chemistry (Sinclair et al., 1998; Fallon et al., 2002, 2003; Rollion-Bard et al., 2003), but function most effectively on elements incorporated directly into the coral skeleton, and may require custom modifications to off-the-shelf analytical systems (Fallon et al., 2003). Incorporation of metals and metalloids into coral skeletons varies as a result of atomic radius – cations with radius similar to that of calcium, such as Ba, Cu, Fe, Pb, Sn, and Zn are most readily incorporated from a dissolved state into the lattice (see Howard and Brown, 1984, for review). Of these, Ba is the best indicator of sedimentation from fluvial sources, and can record spatial and temporal variation in fluvial input far from river mouths, with concentration increasing with proximity to source (Fallon et al., 2003; McCulloch et al., 2003b). Ba/Ca ratios in coral skeletons have documented increased sediment flux to coastal coral reefs through soil erosion associated with agricultural expansion and deforestation (e.g., Anderegg et al., 1997; McCulloch et al., 2003a; Fleitmann et al., 2007). In areas with basaltic soils, soil erosion and sedimentation also results in increased phosphorus delivery to reefs (McCulloch et al., 2003b). Combined with increased anthropogenic nitrogen fixation and delivery to coastal watersheds (Vitousek et al., 1997), this sedimentation is often accompanied by eutrophication.

Chemical analysis of coral skeletons accurately records sedimentation from point or non-point sources containing these metals, such as urban runoff (e.g., Bastidas and Garcia, 1997; Runnalls and Coleman, 2003), offshore oil exploration and production near cold-water coral reefs (e.g., Gass and Roberts, 2006; Lepland and Mortensen, 2008), or some mine tailings, particularly from tin, copper, lead–zinc, and iron mines (e.g., Changsang, 1988; David, 2003), or some gold and silver mines containing aragonite-compatible trace elements.

Other elements, such as Co, Cr, Ni, As, Sb, and Hg are not readily incorporated into the aragonite crystal lattice, and are present in coral skeletons at much lower concentrations, mostly as included sediment particles. These elements, which are often associated with nickel mines or sediment-hosted gold mines, exhibit high spatial variation within coral skeletons, and generally low concentrations in coral skeletons compared to their concentrations in reef sediment (Edinger et al., 2008). Although these elements can be directly measured in coral skeletons using LAM-ICPMS,

spatial variation in concentration including sediment particles within the skeleton requires extensive sampling to integrate over a large area of coral skeleton (e.g.,  $50 \times 500 \mu\text{m}$  mask, Fallon et al., 2002), or drilling of subsamples followed by wet-chemical analysis using ICP-AES.

Corals may then be used to monitor sediment influx, river discharge, industrial activity, and several other types of input. Care needs to be taken in chemical analyses of coral skeletons, because exogenous compounds may either be trapped/bound directly into the skeletal structure, or be part of individual sediment grains trapped within skeletal cavities. Notwithstanding this reservation, the information gathered by such geochemical techniques can be extremely useful. In some cases, the temporal resolution of individual events may be excellent. Heikoop et al. (1996) describe the effects of a short-lived eruption of the volcano Gunung Api (“Fire Mountain”) in May 1988, in the Banda Islands, Eastern Indonesia. The ash fall from the eruption was several centimeters in thickness on the reef. Most of the branching corals were killed. Surviving massive corals preserve a Fe-rich band in their skeletons, as well as ash particles trapped within algal borings at a death-regrowth surface. When cleaved open, these corals reveal a striking red band, parallel to the growth surface (Figure 3). Heikoop et al. (1996, p. 291) state: “These proxy records provide information on short-lived, low magnitude, volcanic events which affect but do not totally devastate marine communities. The continual growth records of corals will preserve these geologically instantaneous signals with much better resolution than the bioturbated sediment record. Moreover, large massive corals

**Impacts of Sediment on Coral Reefs, Figure 3** Fe-rich band in a freshly cleaved *Porites* colony, the moment of discovery, Banda Api Indonesia. This band, sampled in 1992, is a record of the eruption of the volcano Gunung Api in 1988. When freshly exposed, the band was dark, almost black. On exposure to open seawater, it oxidized to a red color within minutes. The band is indicated by an arrow. Sponge borings (upper centre–left) are indicated by an “S,” and abundant bivalve borings near the base by a “B.”

may record several such events. Accordingly, in appropriate settings, the periodicity of relatively minor volcanic events may be established in the fossil record with much greater precision than previously permitted."

### How to identify if a reef is sediment-stressed

Globally, coral reefs are threatened by a plethora of anthropogenic and natural factors, and many reefs face multiple stressors (Hughes and Connell, 1999). Disentangling sedimentation from the other stressors with which it usually co-occurs is quite difficult (Fabricius, 2005). The following factors typically occur on reefs subject to sedimentation, with or without other stressors:

1. High siliciclastic content in reef sediment
2. High insoluble residue content in coral skeletons, particularly open-lattice species like massive *Porites*
3. High Ba/Ca ratio in coral skeletons
4. Low recruitment rates of corals, often resulting in size distributions skewed to large colonies
5. Low species diversity of corals, relative to reference sites in same region
6. Low percentage live coral cover, combined with high cover of dead coral (high mortality index)
7. Predominance of stress-tolerant coral species and growth forms, especially multilobate massive colonies
8. High-extension, low-density skeletal growth

### Summary

Sediment input is one of the great killers of coral reefs. The effect is accentuated, because in most situations the sediment is accompanied by dissolved nutrients and organic matter. In many cases, however, the source and the nature of the stress may be identified using a variety of geochemical techniques.

### Acknowledgments

The senior author performed much of the work for this article whilst in residence as a Temminck Fellow at the Natural History Museum in Leiden, Netherlands.

## INDIAN OCEAN REEFS

Eberhard Gischler  
 Frankfurt am Main, Germany

### Definition

The Indian Ocean is bounded by East Africa, South Asia, Indonesia, and Western Australia ([Figure 1](#)). It is the world's second largest coral reef province, after the Pacific Ocean.

### Introduction

The Indian Ocean reef area harbors abundant fringing reefs (East Africa and Madagascar region, India, Indonesia, Western Australia) and numerous atolls (Maldives and Chagos archipelagoes, Cocos Keeling). The only well-developed barrier reef is found around Mayotte in the Comoro Islands ([Figure 1](#)). Submerged banks and reefs are common and include Great Chagos, Saya de Malha, Nazareth, and Seychelles Banks. Stoddart and Yonge (1971) and Stoddart (1973) comprehensively summarized the geomorphology and ecology of Indian Ocean reefs. Montaggioni (2005) recently compiled and analyzed the available data on postglacial reef growth in the Indian and

**Indian Ocean Reefs, Figure 1** Overview map showing major reef locations in the Indian Ocean (from Gischler et al., 2008).

Pacific Oceans. Here, an overview is given of well-studied locations of Madagascar, Mayotte, and the Maldives.

### Madagascar

Numerous coral reefs are developed along the 4,000 km long coastline of Madagascar. They are much more common on the western than the eastern side. The climate is

tropical-subtropical. Strong SW winds predominate throughout the year, and cyclones reach the island frequently. There are numerous fringing reefs along the western Madagascar coast, but the best studied reef system is the offshore Grand Récif near Toliara (formerly Tuléar), at the southwestern coast of Madagascar (Figure 2). Grand Récif, is about 1.5 km across and 25 km long, and the

Indian Ocean Reefs, Figure 2 Map and location of Grand Recif, Madagascar (from Pichon, 1971).

Indian Ocean Reefs, Figure 4 Map of Mayotte (from Zinke et al., 2001).

distance from its outer margin to the shore increases from 2 km in the north to 9 km in the south. The lagoon has an average depth of 10 m, and is connected to the open ocean in the north and south by channels 15 and 20 m deep

respectively (Pichon, 1971). Towards the south, small fringing reefs occur between the mainland and Grand Récif. Pichon (1964, 1978) distinguished seven reef zones across Grand Récif, which are from west to east (1) outer

slope spurs and grooves, (2) outer flat with spurs and grooves, (3) boulder zone, (4) loose-surface flat, (5) sea-grass, and (6) inner slope zones (Figure 3). More than 200 species of Scleractinian corals have been described from Grand Récif. Some authors refer to Grand Récif as a fringing reef (Pichon, 1964, 1971) and others as a barrier reef (Guilcher, 1988, p. 107). Similar problems of terminology exist for Ningaloo Reef on the western Australian coast. Both have sections that are “typical” narrow fringing reefs close to the shore, as well as offshore sections that are much larger, more complex, and separated from the shore by navigable channels up to several kilometers in width.

### Mayotte

The volcanic island of Mayotte in the western Indian Ocean covers an area of 375 km<sup>2</sup> and is 660 m high

(Figure 4). There is a surrounding barrier reef that is up to 2 km wide and interrupted by deep (60–80 m) channels. Four small sand cays occur on the barrier reef. In the NW, the barrier reef has a wide gap. Interestingly, some areas of the barrier reef form ribbons and faroes comparable to marginal reefs in the Maldives (see below). The lagoon inside the barrier reef covers some 1,500 km<sup>2</sup>, is up to 15 km wide, and reaches a depth of 80 m (Guilcher, 1971). Coral pinnacle reefs occur within the lagoon; fringing reefs are found at the Mayotte island shore. Dullo et al. (1998) investigated the forereef area in a submersible, and found a spur and groove system with mainly acroporid corals to 20 m depth. Below, a cliff and talus slope occurs. A drowned reef terrace occurs at about 90–100 m depth. From 90 to 190 m depth, a vertical wall transitions into another loose sediment slope extending beyond 300 m of water (Figure 5). Masse et al. (1989) recognized five

Indian Ocean Reefs, Figure 5 Mayotte forereef morphology (from Dullo et al., 1998).

sedimentary facies including (1) coral-mollusk facies of the outer barrier reef, (2) coral-red algal facies of the reef flat, (3) mollusk-coral and (4) mollusk-*Halimeda* facies of the lagoon, and (5) mollusk-foram facies of the deep lagoonal plains. Guilcher (1971) compared the Mayotte barrier reef with south Pacific (Polynesian) barrier reefs and noted that a major difference is the lack of a distinct algal ridge and larger cays (motu).

## Maldives

The Maldives archipelago is about 1,000 km long and 200 km wide. There are 20 major atolls (Naseer and Hatcher, 2004), which are among the largest in the world (Figure 6). The climate situation is controlled by the Indian monsoon system with the windy and wet months of May–October and the dry and calm months of November–April. Due to their proximity to the equator, the Maldives are largely free of cyclones. From north to south, marginal reefs get more and more continuous. A total of about 1,500 small islands are located on marginal and lagoonal reefs. Atoll lagoon depths increase from about 50 to 60 m in the north to >80 m in the south (Woodroffe, 2005). Precipitation rates increase in the same direction from 1,650 to 2,400 mm/year. Marginal reefs have ribbon shapes and are in many cases developed as faroes. Faroes also occur within atoll lagoons. Their development has been explained by karst dissolution during Pleistocene sea-level lowstands (Purdy and Bertram, 1993). Reef zonation (Figure 7) based on coral occurrences has been elaborated by Stoddart (1966) and Ciarapica and Passeri (1993). In 1998, the Maldives reefs were heavily affected by the worldwide coral bleaching event (Schuhmacher et al., 2005). Modern sediment distribution is characterized by five facies (Gischler, 2006). Coral grainstone with coralline algae, *Halimeda*, and mollusks occurs on marginal and lagoonal reefs and islands. Skeletal grains in atoll-interior lagoons are mainly mollusks and foraminifera. There are true mudstones, mollusk wackestones, and mollusk-foram packstones, as well as hardgrounds that extend from channels through the atoll reef margins into the adjacent lagoon area.

## Postglacial development

The Holocene fringing reef of Grand Recif (Toliara) is about 15 m thick. Reef growth started 6.6–8.3 kyrs BP and is predominated by robust branching coral, sands, and rubble (Camoin et al., 2004; Montaggioni, 2005). Reef accretion is characterized by a “catch-up” anatomy (see *Holocene Reefs: Thickness and Characteristics*). A drill core on the eastern margin of the Mayotte barrier reef recovered branched *Acropora* to a depth of 21 m and massive *Porites* to 30 m (Camoin et al., 2004). Reef growth started around 9.6 kyrs BP and is characterized by a keep-up anatomy. Zinke et al. (2001, 2005) investigated the lagoonal history of the Mayotte barrier reef lagoon using coring and shallow seismics. They found several sedimentary and seismic sequences including

Indian Ocean Reefs, Figure 6 Map of Maldivian archipelago (from Gischler et al., 2008).

lowstand, transgressive, and highstand systems tracts. The thickness of the sediment fill is up to 20 m, but ample accommodation space remains. Two systematic studies on Holocene reef growth have been performed in the Maldives. Gischler et al. (2008) found Holocene reefs >20 m thick dominated by robust branching acroporids

**Indian Ocean Reefs, Figure 7** Reef zonation in the Maldives. (a) Marginal reef (from Stoddart, 1973). (b) Lagoonal reef (from Spencer Davies et al., 1971).

in marginal sites and massive corals (*Porites*) and sand and rubble facies in lagoonal reef sites. Reef growth started no later than 8.5 kyrs BP. Marginal reefs belong to the keep-up and lagoonal reefs to the catch-up types. Late Pleistocene reef limestone from marine isotope stage 5e (135 kyears BP) underlies the Holocene reefs. Kench et al. (2009) found comparable reef thicknesses and timings of reef growth; however, their cores were dominated

by massive corals, possibly due to the more protected drill sites as compared to the ones of Gischler et al. (2008). In addition, Kench et al. (2009) concluded that late Holocene sea level exceeded the modern one by 0.5 m from 4 kyrs BP, based on microatoll data (Figure 8). Holocene sea level in the Indian Ocean in general is controversial, in that both transgressive and transgressive-regressive curves have been proposed (Camoin et al., 2004; Woodroffe,

**Indian Ocean Reefs, Figure 8** Holocene sea-level curves for western Indian Ocean (from Kench et al., 2009).

2005; Gischler et al., 2008; Kench et al., 2009). More data, especially from the late Holocene, is needed.

## Summary

Indian Ocean reefs include numerous fringing reefs and atolls but only one true barrier reef. Reefs of Toliara (Madagascar), Mayotte, and the Maldivian archipelago are described. These reefs all show zonation and all are

dominated by corals. Massive and branched forms make up the postglacial reefs, which reach thicknesses of up to 30 m with high accretion rates of  $>10$  m/kyr. Modern sediment facies are characterized by skeletal grains. Holocene sea levels obtained from reef studies are controversial, and transgressive and transgressive-regressive curves are discussed.

## INDONESIAN REEFS

Terry Done  
 Australian Institute of Marine Science, QLD, Australia

### Definition

The Republic of Indonesia comprises >17,500 islands, straddling the equator in Southeast Asia. Its total land area is around 2 million km<sup>2</sup>, its territorial seas cover about 3.6 million km<sup>2</sup>, its living coral reefs are estimated to cover ~50,000 km<sup>2</sup>, and fossil reefs are commonplace across the archipelago.

### Introduction

Indonesia is a vast nation with more enclosed seas than any other on earth. Straddling the equator (from 6°N to 11°S) over a north–south distance of 2,210 km (Figure 1a), about the same as the length of the Great Barrier Reef and three times the length of the UK), the country extends 5,271 km from east to west (almost 1 ½ times the distance from New York to Los Angeles). Indonesia's total land-sea area is ~4,573,400 km<sup>2</sup>,

comprising 42% land and 58% sea. The coastline – against which many coral reefs lie – is 95,000 km long (Tomascik et al., 1997), about 45 times longer than Australia's Great Barrier Reef. Total coral reef area has been estimated at 51,000 km<sup>2</sup> (about twice that of the Great Barrier Reef), excluding subsurface reefs and those in remote areas that have not been mapped (Burke et al., 2002). Indonesian seas include 960,000 km<sup>2</sup> of shelf seas <200 m deep (mainly in the west) and 1,694,000 km<sup>2</sup> of deep seas (Dahuri et al., 2009), mainly in the east, but also to the west and south of the narrow shelves bordering the island arc from Sumatra to Nusa Tenggara (Figure 1a). Together, these deep and shallow seas afford a wide range of environments for reef development and populations of coral reef species, from shallow sheltered bays to deep swell-exposed outer slopes (see entry *Coral: Environmental Controls on Growth*). There are also large sections of Indonesia's coasts and seas from which coral reefs are absent. These are of two general types. The first are those sheltered shallow areas facing the inner shelf that are too muddy for corals and thus for the development of coral reefs. The second are a number of long sections of Indian-Ocean-facing coasts, along which corals can be found, but from which major reef development is excluded, probably by extreme wave forces (Spalding et al., 2001). In addition to the present environmental diversity, the effects of eustatic sea-level changes and high tectonism contribute to the diversity of form and biotic composition of Indonesia's coral reefs (Hutomo and Moosa, 2005). Four major tectonic plates meet in Indonesian seas (Australian, Eurasian, Philippines, and the Pacific; Figure 1b), and the consequent high levels of volcanism and seismicity have great significance for the size, development, and morphology of Indonesia's coral reefs, both fossil and modern.

The main focus of this entry is physical geography – the extent, distribution, and types of coral reefs, and the variability of their environmental settings and historical drivers. In Indonesia, people are important drivers of living reef condition and productivity: much of Indonesia's population of more than 250 million people lives close to reefs, harvests reef resources (food, building materials (Figure 3)), and modifies reef habitat and water quality through dredging and land-use in adjacent catchments. The people–reef interaction is the focus of much research, management, and conservation attention (Nontji, 2002; Anon, 2009).

### Biodiversity

Indonesia is at the center of the “Coral Triangle” containing Earth's greatest biodiversity of marine life (e.g., 76% of all corals; 37% of all coral reef fishes and similar proportions of other marine life, Hoeksema, 2007; Hoegh-Guldberg et al., 2009). The greatest diversity of corals and fishes occurs in the deeper seas of Eastern Indonesia on the Pacific Plate (“Wallacea”) (see entry *East Indies Triangle of Biodiversity*), which is where the most Indo-West Pacific species show overlaps in their

distribution ranges. Some larval dispersing crustacea (Barber et al., 2000) and coral species (Hoeksema, 2007) that are abundant in Wallacea do not occur on Sunda Shelf reefs in the west, suggesting there have been limits to their dispersal and/or population establishment in the transgression following the LGM (17–18 kya). However, while there are some coral species that do have distributions that overlap only with the Indian Ocean or only with the Pacific Ocean (Wallace and Wolstenholme, 1998), there are many other coral species that do occur across the archipelago (Edinger et al., 2000; Wallace and Wolstenholme, 1998).

Whereas the origins of this diversity is explained in large part in terms of sea-level and oceanographic changes and isolation leading to speciation in geological and evolutionary time (Barber et al., 2000; see entry *East Indies Triangle of Biodiversity*), a great deal of the diversity and productivity of marine life in Indonesia today (Tomascik et al., 1997; Hoeksema, 2007) is maintained by the immense extent and variety of its coral reefs. Despite the drying of Indonesia's continental shelves during Pleistocene lowstands (Figure 1b), the dominant corals on modern reefs on the shallow Sunda Shelf in the

west are largely similar to those of the open ocean reefs of eastern Indonesia (Edinger et al., 2000). The seafloor topographic highs and submarine slopes of the latter area apparently afforded sufficient extent and temporal continuity of suitable habitat for reef biota to survive the lowstands. Moreover, there has clearly been adequate time since the last glacial maximum for all the vital functional groups of reef biota (Done et al., 1996) to disperse to and develop reefs in the newly submerging shelves 20–7 kya, albeit with the local variability in species composition referred to above (Barber et al., 2000; Hoeksema, 2007).

### Environmental setting

Indonesia's vast extent and physical complexity provide a range of environmental settings for coral reefs almost as wide as that of the entire global coral reef domain. Ocean waves and swells with long fetches across the Indian Ocean break on reefs around islands along the west coast of Sumatra and on headlands and semi-enclosed bays on the south coast of Java. Cool nutrient-rich waters regularly upwell onto western and southern margins of

**Indonesian Reefs, Figure 2** Modeled and satellite remote sensed sea surface temperatures (SST) and modelled currents. (a) March 27, 2004 (no upwelling). Produced by: C. Steinberg, Australian Institute of Marine Science, using Bran1 database <http://www.marine.csiro.au/blueink/> (b) Bran1 representation of SST on Nov 22, 1997 during a period of strong upwelling. (c) AVHRR SST. Source of (b) and (c): Oke et al., 2005.

Sumatra, Java, and Nusa Tenggara, while waters only a few kilometers away can be near 30°C on the same day (Figure 2). Reefs in the Indonesian Throughflow (ITF; Figure 1a) are regularly exposed to southward surface currents of  $\sim 0.8 \text{ m s}^{-1}$  (week-long average; Gordon et al., 2003), whereas many reefs in deep embayments, away from the ITF are subject only to weak tidal flows. Reefs throughout most of the country are periodically exposed to currents and waves generated by monsoonal winds. Only a small proportion of Indonesia is in the cyclone belt ( $>7^\circ\text{S}$ ), so only the southernmost reefs are exposed to the extreme physical destruction wrought by cyclones (see entry *Tropical Cyclone/Hurricane*). An example is Nusa Tenggara (Figure 1a), which is a region of cyclone genesis for cyclones that move onto Australia's north-west coast, and where destructive seas are important drivers of coral mortality and reef growth (Tomascik et al., 1997). Massive waves (see entry *Tsunami*) and seismic displacement (up or down) are also commonplace (Richmond et al., 2006; Briggs et al., 2006) (see entry *Earthquakes and Emergence or Submergence of Coral Reefs*). For example, the earthquake of December 26, 2004 (9.3 on the Richter scale) caused the death of 300,000 people across the Indian Ocean. The epicenter was just off the west coast of Sumatra and initial reports

from satellite observations suggested 97,250 km of reef was affected in Indonesia with a loss of 3,061 ha valued at \$332 million (Campbell et al., 2007). However, more detailed survey subsequently indicated that the near-field damage was much less than originally estimated. Both uplift and subsidence were recorded but Hagan et al. (2007) suggested that much of the damage was caused by terrestrial debris washed onto the reef, and that the reefs were already in poor condition due to anthropogenic causes (Hagan et al., 2007), "...the initial damage to corals, while occasionally spectacular, was surprisingly limited and trivial when compared to pre-existing damage most probably caused by destructive fishing practices" (Campbell et al., 2007, p. 55).

### Fossil reefs

Fossil reefs abound in Indonesia, reflecting both tectonic uplift and eustatic sea-level changes. On Atauro (Chappell and Veeh, 1978), Alor (Hantoro et al., 1994), and Sumba Islands (Verstappen, 1997), for example, there are Pleistocene coral reef terraces up to 475 m above sea level. The highest and oldest of these terraces formed 1000 kya suggesting average uplift rates of,  $0.49\text{--}1.0 \text{ mm y}^{-1}$ . The lower terraces correspond with high sea levels of specific interglacial stages at 275–117 kya, 344–228 kya,

397–322 kya, and 603–584 kya (Pirazzoli et al., 1991). There is also widespread occurrence of younger fossil reefs to ~5 m above current sea level representing upward limits of reef growth determined by Holocene sea-levels.

The 5 m reef is believed to have been formed at a high stand about 5.8 kya, and there are fossil coral heads (Figure 3c) and reefs interpreted as representing progressively lower sea-level highs at 4 kya, 2.6–2.9 kya,

and 0.2 kya (Tjia, 1996). Finally, there are geologic features caused by events within recent human memory. For example, the major earthquake of March 2005 lifted reefs off the east coast of the island of Nias by  $>2$  m, and sunk those on its west coast by  $\sim 0.25$  m (Briggs et al., 2006).

### Living reefs

Indonesia's coral reefs include all the major morphological forms: viz. atolls, barrier reefs, patch reefs, and fringing reefs (Tomascik et al., 1997). There are also coral communities (no tendency for reef development) and incipient reefs (which do accrete framework, but have not yet built substantive framework; see entry *Coral Reef, Definition*) on most coastal hard substrata (fluvial bars; rocky shores). Coral communities and incipient reefs occur on stable shores of active volcanoes (Tomascik et al., 1996; Starger et al., 2010), while true fringing reefs and barrier reefs occur only on non-volcanic islands and older quiescent volcanoes. Indonesia's "atolls" (annular forms with enclosed lagoon) occur in the currently tectonically active Banda Sea (Figure 1a), but many are probably sitting on non-volcanic basements. There is a preponderance of uplifted reefs in the area that suggests that over geological time scales, Indonesia's atoll basements are frequently subject to diastrophic deformation (Tomascik et al., 1997). Indonesian atolls may be examples of those for which Purdy and Winterer (2000) invoke dissolution caused by annual monsoon rains as major drivers of lagoon depths. The process is highly plausible for atolls in Indonesia, whose antecedent foundations would have been exposed during LGM to annual rainfall presumably measured in meters (assuming, after Purdy and Winterer (2000) that today's rainfall is a good proxy for LGM rainfall). In this regard, Indonesia's atolls contrast both with Darwin's classic genetic sequence of atoll formation (which does not rely on massive dissolution), and with Grigg's (1982) Darwin Point elaboration, (which involves plate movement into less hospitable waters (see entries *Darwin, Charles (1809–1882); Darwin Point; Subsidence Hypotheses of Reef Development and Volcanic Loading and Isostasy*)). In Indonesia, reef development also occurs in turbid waters along some open sedimentary coastlines, within muddy coastal embayments, and around high continental islands. In these situations, frequently in shallow-water (5–20 m) depths, reef growth can be very rapid, with reefs reaching sea level and undergoing significant seaward progradation over century to millennial time scales (see entry *Turbid Zone and Terrigenous Sediment Influenced Reefs*).

### Sumatra

The wave-exposed west-facing coasts of Sumatra facing the Indian Ocean (Figure 1a) are characterized by steep headlands and intervening beach-ridge coastal plains and deeply incised river valleys (Richmond et al., 2006). There are patchy fringing coral reefs in coastal bays and nearshore continental islands, but much stronger reef

growth occurs on the continental islands that extend in a line from Simeulue, through Nias, Banyak, Batu, and Mentawai Islands. These islands are separated from Sumatra by marine basins 1–2 km deep, and all have substantial fringing coral reefs. On open west-facing coasts, these reefs are usually patchy and narrow, but semi-enclosed bays on all sides, and on points that deflect ocean waves, they are up to several hundred meters wide. A few kilometers to the west of Nias on the 200 m isobath are the inhabited Hinako Islands (low, vegetated raised coral reefs with wide reefs; Figure 3c). At Sumatra's northern tip, modest fringing reefs are developed on continental islands of Pulau Aceh and Pulau Weh. However, reefs are absent from the entire 1,700 km of Sumatra's north and north-east facing coasts, which are mainly muddy prograding shores with mangrove forests. There are well-developed fringing reefs in the islands of the Riau Archipelago and Natuna Sea, between Sumatra and Kalimantan.

### Java

Java's reefs primarily comprise coral cays and island fringing reefs offshore from its muddy north coast. The 700 reefs of Kepulauan Seribu, 20–80 km offshore from Jakarta, are coral cays. These reefs are characterized by a gradient of increasing coral diversity and water clarity with increasing distance offshore (DeVantier et al., 1995). The Karimunjawa group (70 islands about 80 km offshore from central Java), are high islands with well-developed fringing reefs, barriers, and lagoons. There are reefs scattered along the 800 km south coast of Java, favoring points where waves approach at oblique angles. Limited reef-flat development elsewhere along this shore is probably a result of extremely strong waves (Spalding et al., 2001). However there are well-developed fringing reefs along Java's short and more sheltered east coast (Spalding et al., 2001).

### Kalimantan

The Mahakam River, which drains almost one third of East Kalimantan, is a major influence on reef distribution. On the east coast, there are only occasional fringing reefs and offshore patch reefs, for example, in front of Balikpapan Bay. Immediately to the north of the Mahakam Delta, there are well-developed fringing reefs, interrupted by other rivers, while northwards to the border with Sabah the coastline is reefless, dominated by major river deltas. The southwestern coast of South Kalimantan is also largely deltaic and devoid of reefs, but to the east and north of Tanjung Selatan there is some fringing-reef development. There are three barrier-reef systems east of Kalimantan: the submerged Great Sunda Barrier Reef (630 km) lies 60 km offshore along the 200 m isobath, and smaller barrier reefs are found north of the Mahakam delta. North of the Mangkalihat Peninsula and 60 km offshore are three major lagoonal shelf reefs: Muaras (288 km<sup>2</sup>), Maratua

(690 km<sup>2</sup>), and Kakaban (21 km<sup>2</sup>). The latter two have raised limestone rims up to 120 m above sea level.

### Sulawesi

The island of Sulawesi (coastline 4,750 km), probably has the largest coral-reef area in Indonesia. A very high proportion of its coastline and offshore islands is fringed with reefs often ~200 m wide. Tomascik et al. (1997) describe 34 individual barrier reefs around the islands with a total length of 2,084 km, that is, bordering 43% of Sulawesi's coastline, and of which eight are more than 100 km long. These very long barrier reefs are submerged over most of their lengths, but many shorter ones a few kilometers offshore of islands are classic intertidal reefs separated from the shore by navigable lagoons (see entry *Coral Reef, Definition*). The Spermonde Archipelago comprises some small-platform reefs with cays, many submerged platform reefs, and a fragmented submerged barrier reef that lies 45–65 km offshore. There are also long submerged barrier reefs running eastwards from the volcanic Togian Islands (165 km) and along the southern margins of the Banggai Islands (175 km), including faro reefs similar to those found in the Maldives. Tomascik et al. (1997) describe 27 "atolls" in the waters around Sulawesi, though it is doubtful whether many have developed from volcanic foundations. There are numerous submerged reefs and a further 27 "oceanic" or "platform" reefs at the sea surface, including open-water reefs associated with continental (not always volcanic) islands. They occur in clusters around to the southwest and west of Makassar, the south of Teluk Bone (including World Heritage-nominated Taka Bone Rate), and the southeast, where there is a group of reef-fringed high islands known collectively as Wakatobi (Pulau Wangiwangi; P. Kaledupa; P. Tomea; P. Binongko).

### Bali and Nusa Tenggara

These islands are all part of one of the world's most active volcanic island arcs, formed at a tectonic plate subduction zone. Fringing reefs are ubiquitous, their morphologies depending on the geomorphology of the coastline and the tectonic history of the islands. Many are narrow structures 30–100 m wide with an intertidal reef flat and very sharp seaward drop-off. However, much wider reefs are also present. For example, around Bali, van Woesik (1997) indicates the fringing reefs extend 500 m from the shoreline. There are also well-developed reefs at Komodo National Park (Djohani et al., 1999) and Lembata Island, with three active volcanoes (Tomascik et al., 1997). Discontinuous fringing reefs with well-developed spur and groove systems occur along the high energy southern shore of the Nusa Tenggara islands. On the more sheltered western and north-western sides facing the Flores Sea, the reefs are more continuous and up to 800 m wide, with dense growth of sea grasses on the flats. Some nine barrier reefs are listed by Tomascik et al. (1997) in this region, though some are very close to shore and difficult to differentiate from fringing reefs with "boat

channels." At least a third of the north coast of Flores is bordered by such a barrier with other significant barriers on both north and south coasts of Sumbawa and the north coast of Lombok. No open water reefs are found to the south of the island arc, probably because of the great depth of water. There are only two in the Flores/Banda Sea area off the northern shores of Flores (Karang Serbete and Gosong Boni).

### Maluku

The coral reefs of Maluku are regarded as the biologically richest in the world (Hoeksema, 2007). Fringing reefs thrive in the turbid waters of the Aru Islands, which consist of six main islands and 79 smaller islands separated by long narrow channels. Major fringing-reef development is along the shallow east coast where the reef can be up to 1.5 km wide, but narrower reefs are found along the remaining coastlines, except the southern part of the west coast. There are 15 reported barrier reefs with a total length of 425 km, but so little of this area has been surveyed in detail that this is probably an underestimate. They are associated with the islands of Morotai, Halmahera, Seram, Gorong, Kofiau, Obimayor, Batanme, Nila, and Tanimbar. Open water reefs, very few if any of which are true atolls, are found in the Banda Sea (Kepulauan Lucipara and Kep. Penyu), and to the south and east of Halmahera.

### West Papua

West Papua, with a coastline length of 4,200 km, remains one of the least studied areas in Indonesia. Because of high run-off and sediment yield, fringing reefs are missing from significant sections of the coastline, but in other places, fringing reefs appear to be very continuous. Tomascik et al. (1997) suggested the following as the major areas:

- The north coast from Jayapura to the border
- Jayapura to Tg. Kandara, where the reefs are 300–400 m wide and westwards to Sarmi
- All the islands of Cenderawasih Bay, 50–100 m wide
- On the south coast west of the Omba River
- The southern side of the "Bird's Neck" between Lakahia Bay and Kamarau Bay
- Between Tg. Tongerai and Tg. Kirana, the coastlines along the foothills of Kumafa and Fakfak Mountains, and
- The northern side of the "Bird's Head," which appears to be suitable for fringing reefs.

More recent studies have more than verified Tomascik et al.'s predictions. For example, more than 500 species of reef building corals have been reported at Raja Ampat (Turak and DeVantier, 2003), making it "the most diverse area of the Indo-Pacific" on record for corals.

### Summary

Indonesia's territorial seas are the world's largest contiguous coral reef domain under the sovereignty of a single

country. All major morphological forms of coral reef occur in Indonesian waters: atolls, barrier, fringing, platform, as well as coral communities (not building reefs), and incipient coral reefs. Many of the major barrier reefs are submerged structures that rise to depths of 15–10 m from near the 200 m isobath, reflecting their former existence as fringing reefs during periods of low sea level, brought to an end by the 120 m rise in sea level following the last glacial maximum, 18–17 kya. Most, if not all, “atolls” occur on sea-floor highs whose geology is not known, but is likely in most cases not to be volcanic. In Indonesia, atoll forms may, therefore, be better described as lagoonal platform reefs. Volcanic islands are extremely abundant, many with good reef development, but many also too active and/or too young to have permitted substantial reef development. There are abundant raised fossil reef terraces across the country, a result of upward displacement of islands by subduction beneath them of the Indian Ocean plate, by Pleistocene and Holocene sea-level fluctuations, and by seismic uplift. There are large and thriving modern reefs in both the deep eastern and shallow western parts of Indonesia’s enclosed seas, as well as along the south and westward shores facing the Indian Ocean. The biodiversity of Indonesia’s reefs – the highest of anywhere in the world – represents the overlap of four types of distributions: Indian Ocean, Pacific Ocean, Indian plus Pacific Ocean, and endemics (Wallace and Wolstenholme, 1998; Hoeksema, 2007). These overlaps are believed to be outcomes of geological history, sea-level fluctuations, and the barrier to west to east dispersal provided by the Indonesian Throughflow, which moves five times as much water from east to west than in the opposite direction (Gordon et al., 2003). Current reef diversity and productivity are sustained by an extremely complex physical and oceanographic setting.

## INFRASTRUCTURE AND REEF ISLANDS

---

Michael R. Gourlay  
 The University of Queensland, Brisbane, QLD, Australia

### Definitions

Infrastructure: Structures and facilities required to support human activities.

Reef Islands: (1) The portions of modern coral reefs permanently above high tide level – includes atoll islands (motus), coral cays, low wooded islands, mangrove islands. (2) Continental islands or raised ancient reefs completely or mostly surrounded by modern coral reefs or located within a coral reef region. These islands may have sedimentary margins which have formed or behave in similar ways to the various reef islands listed in definition (1).

### Introduction

Reef islands have been occupied by humans for many centuries, requiring the provision of various forms of infrastructure to support their communities. Groups of permanent settlements with similar cultural identity may form independent island nations, such as the Maldives in

the Indian Ocean ([Figure 1](#)), Kiribati, and other island nations in the Pacific and the Caribbean. Other regional groups of reef islands form parts of larger nations as in Indonesia, the Philippines or the Torres Strait Islands, the latter being politically part of Australia.

In other cases, human occupation was or is transient as infrastructure is set up to support some form of extractive industry such as guano mining for agricultural purposes, beche-de-mer fishing, or turtle canning. Tourism is a more recent and possibly less transient use of reef islands (Hopley et al., 2007).

Reefs and reef islands have been and continue to be used as platforms for structures and facilities needed as navigation aids and for communications and weather forecasting.

Reef islands (definition (1)) are inherently unstable and change their size, shape, elevation and location in response to short-term changes in wind, wave and current patterns and to long-term changes in sea levels. Their low elevation makes them particularly threatened by rising sea levels associated with climate change (see Chapters *Climate Change: Impact of Sea Level Rise on Reef Flat Zonation and Productivity*; *Climate Change: Impact on Coral Reef Coasts*).

### Infrastructure for reef island communities

Inhabited reef islands require most types of basic infrastructure associated with coastal communities, including the provision of transport or access to the island, shelter in appropriate buildings, water supply, waste disposal (sewage and refuse disposal), electric power, communications, roads, and sea defence. Provision of much of this infrastructure involves changing the natural environment. Some activities, such as reclamations to enlarge islands for resort and other development that may be permitted in island nations, e.g., the Maldives (Bodge and Howard, 2007), are not allowed in conservation regions, e.g., Great Barrier Reef Marine Park.

Transport to and from an island requires:

- Appropriate mooring and/or harbor facilities for modern vessels, involving dredging of entrance channels and harbor basins through the reefs surrounding islands ([Figure 2](#)).
- Airfields and helipads constructed in lagoons or on reefs and islands ([Figure 3](#)).

Dredging harbor basins in reefs inevitably releases the silt and mud trapped in the cavities of the reef substrate ([Figure 4](#)) and, if this process is uncontrolled, significant damage may occur to the reef environment in the vicinity of the harbor works (Gourlay and Jell, 1993). Growth of corals may be inhibited by light reduction in turbid water or by smothering by deposited sediments. Artificial entrance channels to both dredged basins and atoll lagoons can concentrate and/or increase tidal flows on/off the reef or in/out of the lagoon with consequent long term changes to the reef or lagoon environment ([Figure 2](#)) (Maragos, 1993; Gourlay, 1995; Gourlay and Hacker, 2008). In some

places, e.g., the Maldives, sea planes provide a major form of interisland transport and their operation may require the removal of patch reefs and other obstructions from landing areas in lagoons.

Construction of airfields and roads on reef islands and surrounding reefs or in adjoining lagoons requires supplies of suitable filling material. In some cases, this will have to be coralline sand and gravel dredged from adjoining lagoons and in other cases terrigenous material quarried from an adjoining continental island. While coralline

sand and gravel filling material does not meet all the usually required technical specifications – it lacks fine sands – it can be used effectively for such reclamations (Bullen, 1991). All such dredging and reclamation projects pose the risk of undesirable environmental impacts.

Location of buildings on reef islands usually requires removal of vegetation and thereby interference with nesting sites for birds and turtles. Moreover, buildings need to be located away from the unstable portions of the island's shoreline. The most stable central portion of

**Infrastructure and Reef Islands, Figure 3** Lady Elliot Island – southern GBR. Natural vegetation is recovering after nineteenth century guano mining and construction of airstrip in late twentieth century. Photo © QuintonMarais.com 2006.

a coral cay inevitably also is the location of the largest trees which are the favored nesting sites for some bird species.

Fresh water may have to be imported, collected from rainfall, pumped from underlying fresh water lenses, or obtained by desalination of sea water. In some situations where fresh water is scarce, salt water can be used for some purposes, e.g., flushing toilets and firefighting. In other cases, appropriately treated sewage effluent can be used to water gardens and lawns.

Waste disposal creates problems. For example, at Green Island, the most visited cay on the GBR, sewage used to be discharged onto the reef flat. During a period of more than 30 years of sewage discharge, the area of seagrass on the reef flat expanded from 900 to 130,000 m<sup>2</sup> (Hopley, 1982). These seagrass beds trapped sand eroded from the cay's beaches, preventing its return to the cay and thus contributing to the latter's continuing loss of sand (BPAQ, 1989).

Untreated sewage and agricultural fertilisers from nearby mainland contain high concentrations of nitrogen and phosphorous and these nutrients impose stress upon corals; encourage competition from marine grasses, algae and filter feeders such as sponges; ultimately they weaken the coral leading to its destruction (Bell, 1991; Kinsey, 1991; Rasmussen et al., 1993). Wave-induced groundwater flow from the ocean through atoll islands can transport liquid wastes, originally discharged from dwellings into the island sediments, into the atoll lagoon, resulting in pollution of lagoonal waters (Nielsen, 1999).

Hence, sewage needs to be treated to a high standard of purity before it can be released into atoll lagoons or ocean waters in the vicinity of coral reefs and islands. General waste, particularly on small reef islands, may have to be removed from the islands for disposal elsewhere.

Electric power usually is generated by local diesel power units since solar and wind power do not operate well with large bird populations. On small islands, or in confined areas, diesel generators can create unacceptable noise problems.

Construction of causeways linking atoll islands may result in higher ocean water levels on the seaward side of these islands and stronger currents in the residual channels between them, causing overtopping, erosion and destruction of both islands and causeways. Causeways also block exchange between ocean and lagoon waters, reduce the flushing of a lagoon and hence cause deterioration of water quality in lagoons (Coleman, 1991, Maragos, 1993).

The shoreline alignments of coral cays change with changing wind and wave conditions with the most vulnerable part of the cay being the apparently sheltered lee side.

In the Great Barrier Reef (GBR) region, the tourist resorts on both Heron and Green Islands have required sea defence works, such as groynes and seawalls (Figures 5 and 6), as well as beach replenishment, to protect infrastructure constructed in earlier times on land which was located on the potentially unstable part of the cay (Gourlay, 1983). As on many mainland coasts, such works are not always successful because of their inappropriate nature, inadequate design and lack of environmental information, particularly wave and current data. Moreover, it is essential that designers of such works recognize the unique circulatory nature of the coastal processes operating around small reef islands (Kench et al., 2003). Properly designed coastal engineering works on small reef islands will require relatively more extensive investigations and hence will be more costly than similar works in more benign environments (Gourlay et al., 2004, p. 24).

### Flooding and disaster protection

Reef islands are located in the tropics and those between 10° and 30° latitude are subject to the impact of tropical cyclones (hurricanes, typhoons). All are potentially vulnerable to tsunamis. This means that reef island communities need appropriate disaster management plans.

Low-lying reef islands, such as coral cays, are vulnerable to flooding from storm surges, swells from distant storms and tsunamis. Storm surges are associated with cyclone-generated wind waves and strong winds. Shoreline erosion, destruction of trees and other vegetation, as well as damage to infrastructure, can be expected with a direct hit or near miss cyclone. The risk of this occurring

**Infrastructure and Reef Islands, Figure 5** Seawall constructed at Heron Island, southern GBR, to protect resort buildings from shoreline erosion. Seawall construction, using local materials and cement, began in mid-1950s and is ongoing as required. Photo: Jennifer Hacker, January 1994.

**Infrastructure and Reef Islands, Figure 6** Seawall, designed according to engineering principles using interlocking precast concrete blocks, constructed to prevent shoreline erosion on the leeside of Green Island, northern GBR. Photo: Michael Gourlay, May 2001.

varies in different regions and depends upon the frequency and intensity of cyclones, the tidal range, and the elevation of the islands. Severe tropical cyclones are more likely to occur in latitudes  $15^{\circ}$  to  $20^{\circ}$  than in lower latitudes. Large tidal ranges reduce the risk of flooding from storm surges. Hence, cays within the GBR, where tidal ranges are generally at least 2 m, are less likely to be flooded than the ones in the Caribbean or the central Pacific and Indian Oceans, where tidal ranges are generally significantly less than 1 m. For example, if the peak surge and largest waves occur at low tide in the southern GBR, damage to infrastructure will be caused largely by wind and rain but not by waves. However, if the peak conditions occur at a high spring tide (range ca 3 m), massive destruction of both natural island geomorphology and human infrastructure almost certainly will occur with probable loss of life if prior evacuation of humans has not been possible.

Distant storms, hundreds or even a few thousand kilometers away from a reef island, can generate swells which break on the island's protecting reef causing significant wave set-up, particularly in microtidal environments. On some occasions, the resulting higher water levels and larger waves on the reef top will erode beaches, damage harbor breakwaters and flood settlements on low-lying land behind the reef (see Chapter *Wave Set-Up*).

Tsunamis also may occur under clear skies and without large storm waves or strong winds. Inundation may be total such as that which occurred in the low-lying reef islands of the Maldives in December 2004. Infrastructure damage will occur but loss of life may not be large, if adequate warnings are possible and people can be evacuated to high ground or specially constructed refuge towers or even boats in open water to ride out of the passage of the tsunami. Total inundation of a reef island by storm surge

**Infrastructure and Reef Islands, Figure 7** Raine Island beacon constructed in 1844 on the outer northern GBR, showing erosion of cay rock foundation by nesting turtles. Photo: David Hopley, March 1977.

or tsunami is likely to pollute island freshwater aquifers (Goffredo et al., 2007; Srinivas and Nakagawa, 2008).

### Infrastructure for navigation and weather monitoring

The GBR is the largest system of coral reefs in the world and adjoins a well-populated coastal region, exporting large quantities of minerals and agricultural products. Many ships need to navigate its waters and provision of navigation aids commenced in the middle of the nineteenth century.

Raine Island is the largest cay on the outer reefs of the GBR, located at the entrance to a passage from the Coral Sea to inner GBR waters. The earliest beacon on the GBR was constructed on this island by British sailors and convicts from New South Wales in 1844 using local cay rock (Figure 7). Subsequently, as steamships replaced sailing ships, the sheltered inner passage became the preferred course for shipping, initially sailing in daylight hours and anchoring at night. More navigation aids were needed – unlit wooden beacons and even coconut palms planted on coral cays. As pressure developed for shorter

passage times, together with increasing loss of life from vessels hitting reefs, manned lightships and lighthouses were installed (Figure 8). During the twentieth century, automatic lights progressively replaced manned lightships and lighthouses. Subsequently, in the late twentieth century visible lights were progressively replaced by radar reflecting beacons. All these navigation aids were located in the regions subject to cyclonic winds and waves. Some of them were located on small coral cays or reefs without islands.

During the 1970s, the need for weather forecasting data, particularly for tropical cyclones, led to the establishment of automatic weather stations on various reefs and cays in the Coral Sea eastward of the GBR.

All these structures located on reefs and cays need to be designed and constructed with special consideration of the tropical coral reef environment. Coral cays cannot be relied upon to provide stable platforms for foundations, because of their unstable shorelines (Figure 9). Coral reefs provide a very heterogeneous substrate of hard limestone, softer detrital material and cavities full of coral mud

**Infrastructure and Reef Islands, Figure 8** North Reef Lighthouse, southern GBR. Caisson foundation on reef flat ensures structure's stability as unstable sand cay changes location. Photo: Isobel Bennett, December 1950.

**Infrastructure and Reef Islands, Figure 9** Automatic weather station constructed on Gannet Cay, in Swain Reefs, GBR, has been rebuilt on pile foundations after the original structure's shallow foundations had subsided when the cay changed location. Photo: Peter Flood, early 1980s.

(Hopley, 1991; Simmons, 1991). Sometimes, piles cannot be driven into the reef top; other times, piles do not reach a firm substrate. Raft-type foundations spreading the load over a larger surface area of the reef top have been adopted in many situations, while the most recent new structures are large cylinder caissons located in inter-reefal waters of the continental shelf.

The highly corrosive tropical marine environment requires either the use of expensive corrosion-resistant materials or frequent maintenance and replacement of structures. Furthermore, birds and the guano they produce are likely to interfere with the operation of instruments.

## Conclusion

Special care is required when locating, designing, constructing, and maintaining infrastructure in coral reef regions. Infrastructure located on reefs and unstable reef islands inevitably affects the natural environment and is also affected by the harsh marine environment in these regions. In most cases, the site-specific investigation of the waves, currents and other factors affecting this infrastructure will be complex and hence its cost will comprise a relatively larger proportion of the total project cost compared with similar works located in more benign coastal environments. These low-lying islands and their infrastructure are also vulnerable to flooding from storm surges, wave set-up and tsunamis, as well as rising sea levels.

## INTERNAL CIRCULATION

Kevin E. Parnell

James Cook University, Townsville, QLD, Australia

### Synonyms

Pore-water dynamics; Reef framework circulation

### Definition

Internal circulation is the movement of water through the reef framework caused by hydraulic gradients at a range of time and space scales.

### Introduction

The driving mechanisms, the pathways, and the speeds of water movement through the reef framework are important for reef diagenesis, for the mass transport of solutes (such as nutrients) between the sub-surface (pore) waters, the benthic layer, and the surface waters (with biological and geochemical implications), and for the understanding of coral cay and fringing reef geohydrology (Buddemeier and Oberdorfer, 1988). For laminar flow, Darcy's Law that relates water movement through a homogeneous porous media to the hydraulic gradient and the hydraulic conductivity (primarily a function of permeability) applies. The assumption of laminar flow is likely to hold for all but a few environments, such as in large cavities in the vicinity of breaking waves. Coral reef environments, however, rarely have homogeneous framework at all but the smallest spatial scales, with sometimes extreme differences in both the horizontal and the vertical. Cavities and loose sediments composed of rubble and/or coarse sands exist alongside solid coral heads and densely packed fine sediments, meaning that flows can be variable over very short distances. Advective flows clearly dominate internal circulation, but molecular diffusion, with

diffusion coefficients in the order of  $10^{-10}$ – $10^{-9}$   $\text{ms}^{-2}$  (Li and Gregory, 1974) must also be recognized.

### Driving mechanisms

A model of the principal driving mechanisms for internal circulation is presented by Buddemeier and Oberdorfer (1988) (Figure 1). They also suggest upper limit velocities associated with the various mechanisms, and these are reported in brackets in relation to the various mechanisms in the following discussion.

Hydraulic gradients caused by wave set-up are capable of sustaining uni-directional flows ( $10^{-4}$   $\text{ms}^{-1}$ ) through the reef framework. Wave setup generated hydraulic gradients can be substantial, but will tend to zero under calm wave conditions or at low tide. Although they have the potential to generate significant internal circulation, the zone in which the gradient is highest is frequently highly lithified with a relatively impermeable surface (such as a pavement of crustose coralline algae), which may inhibit the flow of water into the framework. When water is driven by wave processes into the lagoon, ponding may result in a hydraulic gradient, which will cause a net lagoon to ocean flow ( $10^{-5}$ – $10^{-4}$   $\text{ms}^{-1}$ ), suggested by Buddemeier and Oberdorfer (1988) to be preferentially directed through deeper reef framework, and which is suggested by them to be capable of flushing large volumes of high-permeability aquifer on the scale of years to decades. Localized steeper hydraulic gradients may form for short periods, particularly during periods of outgoing tides, causing shallow flows orders of magnitude higher than the long-term ponding-driven flows. Ponding generated flow is superimposed on flows in the framework caused by other regional currents (up to  $10^{-3}$   $\text{ms}^{-1}$ ), including tidal currents ( $10^{-5}$   $\text{ms}^{-1}$ ) normally oscillatory at the tidal period. A current that forces water against the reef can set up a hydraulic gradient in the permeable reef framework capable of driving pore water flow. Density generated gradients caused by evaporation resulting in

**Internal Circulation, Figure 1** The principal driving mechanisms causing internal circulation of water in a reef framework (after Buddemeier and Oberdorfer, 1988).

high salinity water sinking to the seabed ( $10^{-8} \text{ ms}^{-1}$ ), and thermally driven flows ( $10^{-7} \text{ ms}^{-1}$ ) may be present in some situations. Density driven circulation has been described at a large scale by Leclerc et al. (1999).

Groundwater generated hydraulic gradients resulting from recharge of the freshwater lens on reefs with coral cays (see *Coral Cays – Geohydrology*) can generate slow internal flow ( $10^{-7} \text{ ms}^{-1}$ ). However, in some circumstances where the Ghyben-Herzberg model of the freshwater lens applies, water exits the freshwater lens at the island shoreline, resulting in local flows potentially at least an order of magnitude higher. On fringing reefs, or on reefs with other elevated land adjacent (such as raised coral islands), flows within the adjacent reef framework may be orders of magnitude higher (Parnell, 1986) than in the typical coral cay case. Where the tidal range is significant and the reef flat drains, hydraulic gradients can be significantly greater and water speeds within the framework similarly large.

The primary effect of waves, on the other hand, although capable of causing horizontal flows in surface layers, is to provide a pumping mechanism in the vertical, an important process in the mixing of surface waters and shallow pore waters. Buddemeier and Oberdorfer (1988) suggest speeds of up to  $10^{-2} \text{ ms}^{-1}$ . They demonstrate that a 10 s period wave has the potential to move about  $2 \text{ m}^3$  per  $\text{m}^2$  in and out of the reef surface.

Low frequency, high intensity events such as major storms, tectonic movements, and tsunamis can cause pressures resulting in very significant water flows within the framework and within island sediments. For example, there were many accounts of water bubbling up through the reef framework, and water pressure from underneath causing hard tile floors in houses on coral cay islands to buckle during the 2004 Indian Ocean tsunami (Australian Government Mission and the Maldives Marine Research Centre, 2005). Such events may also cause changes to the structure of individual reefs, permanently altering the hydraulics.

## Experimental studies

In separate studies using fluorescent tracers within the Great Barrier Reef Marine Park, Parnell (1986) reported water movement within a fringing reef flat in the order of  $40 \text{ m day}^{-1}$ , and Oberdorfer and Buddemeier (1986) reported flows of between  $0.2 \text{ m day}^{-1}$  and  $400 \text{ m day}^{-1}$  on a mid shelf reef, but generally being in the order of  $10 \text{ m day}^{-1}$ . Both studies recorded considerable vertical movement within the framework. Most water movement resulted from bulk flow through high permeability zones (voids and rubble) with flows in less permeable framework being much slower. Oberdorfer and Buddemeier (1986) comment on the striking similarities in the results of the two studies, despite the considerable differences in the characteristics of the study locations, concluding that the dominant factor was the heterogeneity of reef sediments. The mid-shelf study also demonstrated large fluxes

of water across the reef surface (in the order of  $10\text{--}1,000 \text{ m}^3$  of water per  $\text{m}^2$  per year).

Numerous studies have concentrated on pore water chemistry, showing that transport in the surface layers is higher than at greater depths, possibly indicating the importance of wave and current driven transport (Tribble et al., 1992; Falter and Sansone, 2000). Some studies have shown extremely short residence times in the upper few meters of the reef framework, attributing the results to wave driven oscillations and “stable head differences of uncertain origin” (Tribble et al., 1992, 1290). McCullough and Land (1992) noted the importance of flow through high permeability zones to reef diagenetic processes.

## Summary

A number of processes result in hydraulic gradients that drive internal circulation on coral reefs at a range of time and space scales, including wave setup, lagoon drainage, tides, and other regional currents, density gradients, groundwater flow, and oscillatory waves. Some flows, such as wave driven pore-water circulation can be very fast, resulting in large water turnover between surface and subsurface sediments, over relatively small areas, whereas at the other end of the spectrum, slow flows driven by other mechanisms affect large volumes of framework, over periods extending from years to geologic time. Field studies have indicated flow through reef framework in the order of tens of meters per day, with water moving in high permeability zones such as cavities and rubble dominating bulk flow.

## INTRINSIC AND EXTRINSIC DRIVERS ON CORAL REEFS

---

Richard B. Aronson  
 Florida Institute of Technology, Melbourne, FL, USA

### Synonyms

Autogenic and allogenic drivers on coral reefs

### Introduction

The morbidity and mortality of reef-building corals have increased worldwide in recent decades, resulting in declines of both living coral cover and the density of coral colonies (Gardner et al., 2003; Bruno and Selig, 2007; Wilkinson, 2008; Schutte et al., 2010). Coral populations have not declined uniformly in time or space, and on some reefs they have remained stable or increased (Porter and Meier, 1992; Murdoch and Aronson, 1999; Aronson et al., 2005); nevertheless, the overall downward trend is indisputable. Because there are so many potential drivers of change on coral reefs, assigning causality to observed patterns is difficult. Ecology strives to ascertain the relative importance of multiple processes that are causing change, rather than to falsify individual explanations or classes of explanation (Quinn and Dunham, 1983). The complexity and scale dependence of pattern and process have led to considerable controversy over what is happening to coral reefs.

### Causal typologies

Ecologists have tended to classify stresses, disturbances, and other processes as either intrinsic or extrinsic. Intrinsic and extrinsic causes can be further classified based on whether they are natural or anthropogenic, and the scales at which they operate (local or regional–global). Strict adherence to these typologies has led to confusion over complex cases. The types, intrinsic and extrinsic, natural and anthropogenic, and local and regional–global, are usefully viewed as the endpoints of continua, rather than as specific targets of classification.

Intrinsic drivers act at small, local spatial scales and include processes such as predation, herbivory, competition, recruitment, juvenile mortality, adult mortality, succession, framework accretion, and framework bioerosion. Changes in these processes generate changes

in reef communities. Ecological succession following a disturbance such as a cyclone (an extrinsic disturbance) would appear to be a clear example of a natural, localized, intrinsic process in coral reef communities. The upward vertical accretion of a reef, which is based on coral growth, raises the living community into shallower water, so in the absence of changes in sea level, the shallowing-upward replacement sequence of corals should be considered autogenic succession (Aronson et al., 1998). (In contrast, reef drowning from rapid sea-level rise, which results in a deepening-upward sequence, is extrinsically driven.) Even succession, however, is not without its classificatory problems. The trajectories of successional sequences will vary in accordance with varying regimes of extrinsic disturbances such as cyclonic activity and global change (Connell, 1978; Done, 1999).

Extrinsic drivers of change on coral reefs include local anthropogenic stresses such as pollution, sedimentation, and nutrient loading (eutrophication); local anthropogenic disturbances such as ship groundings, coral mining, and blast fishing; local natural stresses such as upwelling and the off-platform transport of hot/hypersaline or cold/hyposaline, inimical waters; local natural disturbances such as bioerosion, coral mortality caused by damselfish (Pomacentridae) and other corallivores, tectonic activity, and lava flows; large-scale natural stresses such as increased turbidity following heavy rains and variations in insolation; large-scale anthropogenic stresses such as global warming and ocean acidification; large-scale natural disturbances such as regional disease epidemics of corals and herbivorous echinoids, interruptions in connectivity (i.e., larval supply), and regional outbreaks of the corallivorous seaster *Acanthaster planci*; and large-scale anthropogenic disturbances such as introductions of alien species, increased turbidity from large-scale deforestation, and pan-tropical overfishing. The limited utility of these simplistic classifications for science and management is highlighted by the example of perturbations to larval supply, which can be natural or anthropogenic, and which can act on local to regional spatial scales (Sammarco, 1985; Hughes et al., 2002). Overfishing is clearly anthropogenic, but it can be viewed as a local, regional, or global source of disturbance, and it is extrinsic or intrinsic depending on whether or not human fishers are considered part of the reef ecosystem.

### Evolving models of reef dynamics

Despite these difficulties, broad generalizations are possible about intrinsic and extrinsic drivers of reef dynamics. One widely accepted scenario for the Caribbean region emphasizes the role of human predation in causing degradation of reefs in the 1980s and 1990s. Historical overfishing reduced populations of herbivorous fishes, and then in 1983–1984 a regional disease outbreak decimated the ecologically important echinoid *Diadema antillarum*, with the cascading consequence that declining herbivory released fleshy and frondose macroalgae

(seaweeds) to overgrow corals and dominate reefs (Jackson et al., 2001). This is a hypothesis about local, intrinsic processes responding to extrinsic disturbances (if fishing is considered extrinsic). The scenario is incorrect in this strict form because (1) direct observations showed macroalgal overgrowth of corals to have made a minor contribution to reef degradation (Aronson and Precht, 2006) and (2) contrary to popular opinion among coral reef scientists, the majority of Caribbean reefs are not dominated by macroalgae (Bruno et al., 2009). In a modified version, extrinsic disturbances such as cyclones, which kill corals and open space for algal colonization, interacted with overfishing of herbivores and the loss of *Diadema* to promote a macroalgae-dominated state (Hughes, 1994). This version is also not entirely correct, because sufficient levels of coral mortality can lead to macroalgal dominance even without reductions of herbivores (Ostrander et al., 2000; Williams et al., 2001). In such instances, widespread coral mortality overwhelms the capacity of populations of herbivores to respond sufficiently to forestall macroalgal dominance.

More realistic scenarios of reef degradation emphasize the primary (but not exclusive) role of extrinsic factors, especially infectious coral diseases, thermally induced coral bleaching, and their interactors, in causing coral mortality, with or without ensuing shifts to macroalgal dominance (Hoegh-Guldberg, 1999; Aronson and Precht, 2001, 2006; Hughes et al., 2003). Even remote, quasi-pristine reefs in the Indo-Pacific have been affected by temperature-induced bleaching (Alling et al., 2007; Sandin et al., 2008), emphasizing the now-overriding importance of large-scale, extrinsic influences related to human activities, especially climate change. Intensifying ocean acidification and rising eustatic sea levels are additional, extrinsic effects of climate change that likely will have negative impacts on coral populations in the not-too-distant future (Kleypas et al., 1999; WBGU 2006; Hoegh-Guldberg et al., 2007).

Nutrient loading, whether viewed as intrinsic or extrinsic, appears to be a relatively minor driver of coral and algal dynamics in most cases (Hughes et al., 1999; Aronson and Precht, 2000), but the relationship between top-down consumption (predation and herbivory) and bottom-up, nutrient-driven production is complex (Burkepile and Hay, 2006; Littler et al., 2006). The new consensus on (reduced) herbivory is that its contribution to algal dominance was overstated; however, by controlling macroalgae, herbivorous fish and echinoids can facilitate the recruitment and recovery of coral populations (Bythell et al., 2000; Hughes et al., 2003; Carpenter and Edmunds, 2006; Idjadi et al., 2006; Birrell et al., 2008; Mumby and Harborne, 2010).

## Summary

Coral populations and their recovery from stresses and disturbances will continue to be driven by combinations of factors, but categorizing them as intrinsic or extrinsic

is not as useful as understanding the scales on which they operate. The process or interaction of processes that exerts the strongest influence will by logical necessity be the limiting factor to corals. Addressing regional and global problems such as greenhouse-gas emissions and species introductions will leave local factors to limit coral populations, and vice versa. Simultaneous action on anthropogenic drivers at multiple scales is the only way to mitigate and, hopefully, reverse the degradation of coral reefs.

<sup>2</sup>Physical Sciences Unit, New Orleans, LA, USA

### Synonyms

Atoll lagoon; Backreef lagoon

### Definition

A lagoon is a shallow and generally elongate body of water parallel to the coastline and separated from the open sea by a natural barrier. In siliciclastic sediment systems, this barrier is usually a barrier island, but in carbonate systems, the barrier consists of islands such as the Florida Keys, or more frequently, the barrier is a coral-algal reef of the fringing or barrier type. With atolls, the lagoons can be quite deep and generally circular instead of elongated, and may or may not be associated with a land mass.

### Fringing and barrier reef lagoons

Water circulation in carbonate lagoons is a product of many variables including lagoon dimensions, continuity of the reef barrier, wind speed and direction, wave-swell height and direction, tides, and, to a lesser extent, salinity and water temperature variations. Large-scale ocean currents and high-energy events may also contribute to across-the-reef flow and lagoon circulation (e.g., Coronado et al., 2007). The relevance of each force depends on the interplay between its strength and duration (e.g., wave height, tidal range, and wind speed), reef geometry (water depth and width of the reef crest-flat, and bottom roughness), and the morphology and openness of the lagoon. Figure 1 schematically illustrates two

end-member types of shallow, reef-fronted lagoons where the length of the lagoon ( $L$ ) is usually less than 10–15 km but can extend up to hundreds of kilometers alongshore, such as Ningaloo reef of Western Australia (Hearn and Parker, 1988), while lagoon width ( $W$ ) is generally less than a kilometer or two. These dimensions are typical of fringing reef lagoons both in the Atlantic – Caribbean and in Pacific reef provinces. The reef crest-flat depth  $h_c$  (Figure 1b) affects the way tides, waves, winds, and storm surge interact with the reef (Gourlay, 1994), and the reef crest-flat width ( $D_c$ ), another relevant aspect of reef geometry, also has an impact on wave setup and across-the-reef flow (Symonds et al., 1995; Massel and Brinkman, 2001; Figure 1b). The wider the reef crest-flat (large  $D_c$ ), the more attenuation of cross-reef current velocities and flux into the backreef lagoon.

One reef-lagoon type is characterized by a rather continuous reef with no major breaks. Except in areas where salinities are reduced by freshwater runoff entering the lagoon (Tamura et al., 2007) or in locales where hypersaline conditions develop because of extremely high evaporation rates, e.g., Red Sea (e.g., Friedman, 1968) or Arabian Gulf (e.g., Gunatilaka et al., 1984), waters in fringing reef lagoons are well mixed, have short flushing times (hours–few days, e.g., Hearn and Parker, 1988), and have rather simple circulation patterns. Flow into the lagoon shown in Figure 1a is primarily from water-level setup and overtopping associated with wave breaking on the reef front or crest. The resulting water-level gradient between the reef front and backreef lagoon drives a net flux of ocean water lagoonward. Wave setup in submerged reefs ( $h_c > 0$ ) is approximately 50% of  $H_0$  when  $h_c < 0.7H_0$  but ~10% of  $H_0$  when  $h_c > H_0$  where  $H_0$  represents the off-reef or incident wave height (Gourlay, 1993; Gourlay, 1996a). However, when  $H_0 < 0.4 h_c$ , there is no setup (Gourlay, 1996b). Figure 1b illustrates wave setup on the reef front and the water-level gradient into

**Lagoon Circulation, Figure 1** (a) A shallow lagoon separated from the open ocean by a continuous reef over which water is driven by prevailing waves and wind. Reef-lagoon system length is  $L$  and lagoon width is  $W$ . Where  $W$  is small, a shore-parallel current develops and accelerates toward the lagoon outlet. (b) A cross section of the reef defined in panel A as profile A'-A'' illustrates water-level setup over the reef crest-reef flat as a product of wave breaking. Width of the reef crest-reef flat is defined as  $D_c$  and water depth over the reef crest-reef flat is  $h_c$ . (c) Cross sections A-A' and B-B' of the lagoon shown in panel A illustrate the effect of increasing current velocities on sediment accumulation in the lagoon. Sediment is stored in the low energy part of the lagoon (A-A') but is transported out of the lagoon leaving the exposed lagoon floor where current velocities are strongest at the point of exiting the lagoon (B-B'). Circles in the lagoon on these cross sections represent the relative speed of currents flowing toward the reader and out of the lagoon. (d) This shallow reef type has a discontinuous reef paralleling a backreef shoreline. Tidal currents and refracted waves traveling through gaps between the reef segments interact with the shoreline to create circulation cells that drive sediments into cusped shoreline features. As lagoon width ( $W$ ) increases along with water depth in the lagoon, these circulation cells break down and lagoon circulation is driven primarily by winds and tides.

the backreef lagoon. The early study of Bikini Atoll in the Pacific Ocean by Munk and Sargent (1948) illustrated that waves breaking on the reef drove strong currents (0.25–0.5 m/s) that transported water over the reef and into the lagoon. In a fringing reef setting in the Caribbean, Roberts and Suhayda (1983) measured strong short duration cross-reef currents of >0.4 to 1.8 m/s. Cross-reef currents and volume flux change with the tide. Maximum flux occurs at high tide, but during very low tides (extreme neap tides) and/or off-reef winds, currents may be reversed and water may flow off-reef from the lagoon. Cross-reef flux estimates range from 0.01 to 2.21 m<sup>2</sup>/s (Marsh et al., 1981; Pickard, 1986; Lugo-Fernández et al., 1998, 2004; Gourlay and Colleter, 2005). Wave-driven flows contribute about 45–60% of the total flow in some Pacific and Caribbean reefs (Pickard, 1986; Lugo-Fernández et al., 2004). The remainder of the flow can be attributed to tides, wind stress, and infragravity waves (Lugo-Fernández et al., 1998).

Because of their small amplitudes and long wavelengths or periods (24 and 12 h), the astronomical tides behave as shallow waters waves, the velocities of which depend on amplitude and water depth. Tidal currents reverse direction once or twice a day affecting across-the-reef flow into the lagoon through surge channels and/or larger tidal channels. These linked processes are well established for barrier reef lagoons and especially atoll lagoons where tides impinge unaffected on them from deepwater. If the tidal amplitude is large enough to expose the reef crest-flat, then at low tide water-level gradient will develop that drives an off-reef flux, which depends on the degree of connectivity between the lagoon and adjacent ocean (Yamamoto et al., 1998). Infragravity waves are other shallow waves affecting cross-reef currents. These flows have not been well studied, but have been observed on shelves with reefs (Roberts and Suhayda, 1983; Wolanski, 1994; Lugo-Fernández et al., 1998).

Strong winds either reinforce or oppose the wave- and tidal-driven flows depending on wind direction. In fringing reefs, these effects are accentuated because of the small water depths and the accumulation of water against the coast, which creates a pressure gradient that opposes all inflow at the reef crest. Under such conditions, a two-layer flow may develop if the lagoon is large enough and deep enough to accommodate such a two-layer system, on-reef flow at the surface and off-reef flow near the bottom (Storlazzi et al., 2004). As lagoon–land geometries become more complex and scales increase ( $W$  and  $L$ ) over-the-reef flow becomes less important for driving lagoon circulation. As in the case of the Great Barrier Reef Lagoon near Lizard Island, Frith and Mason (1986) found that circulation was highly coherent with the trade wind for about half the year, but exhibited much more variability (e.g., current reversals) after the trade wind season ended. Wind shifts and tides accounted for this lagoon circulation variability.

Recently, Monismith et al. (2006) describe a cross-reef flux driven by buoyancy created by temperature

differences between the outer reef and lagoon. A similar buoyancy flux should operate on reefs with hypersaline lagoons. Hypersaline conditions are prevalent throughout the reef-lagoon systems of the Red Sea (e.g., Friedman, 1968; Meshal, 1987) and the Arabian Gulf (e.g., Kinsman, 1969; Gunatilaka et al., 1984) because of excessive evaporation.

Inside the lagoon, cross-reef flows, tides, and winds drive a circulation which is constrained by the lagoon's morphology. Figures 1a and 2 illustrate different shallow reef-lagoon geometries and their effects on the lagoon circulation. In the case of a backreef lagoon with limited connectivity with the open ocean, a small width, and a shallow depth, the flow is generally downwind and tends to accelerate as the lagoon outlet is approached (e.g., Roberts, 1980; Tamura et al., 2007; Figure 1). If the reef fronting a shallow lagoon is discontinuous as schematically illustrated in Figure 2, localized circulation cells may develop. Such cells are primarily a product of shoreline currents created by waves refracted through openings between reef segments. These divergent currents at the shoreline create cusped shoreline morphologies. However, when  $W$  increases to beyond narrow fringing reef-lagoon barrier reef scale, these circulation cells break down and lagoon circulation becomes wind- and tide-dominated (as described by Wolanski, 1994).

### Atoll lagoons

Atolls are a special type of reef-lagoon system. Early in the study of oceanic processes and their impacts on reefs and their lagoons, von Arx (1948) conducted a groundbreaking study on lagoon circulation at Bikini and Rongelap Atolls. Circulation in both lagoons was primarily wind-driven in the surface layer with overturning and counter-rotating cells established in the deeper parts of the lagoons. This two-layer flow is illustrated schematically in Figure 2. Strength of both surface and deeper layer circulation was found to vary over a day with changing wind speed. Smaller variations were found to be related to perturbations caused by wave-swell environments, tides, and changes in major ocean currents encountering the atolls. At both Rongelap and Bikini Atolls, over 2% of the lagoon volume was found to be transported into and out of the lagoons on each tidal cycle.

Like their fringing reef and barrier reef counterparts, over-the-reef flux of ocean water to the atoll lagoon is driven by a water-level gradient established primarily by the breaking of waves on the reef front. Atolls located in monsoonal regions, such as the Maldives in the Indian Ocean, receive winds and waves from two dominant directions. It follows that lagoon circulation reversals will occur at the monsoon frequency. An investigation of Cocos (Keeling) islands by Kench (1994), an Indian Ocean Atoll with a lagoon about 3–5 km diameter, determined that atoll structure controlled the pattern of energy distribution and lagoon circulation. In this case, tidal currents drove lagoon circulation and water had a residence

**Lagoon Circulation, Figure 2** (a) A schematic plan view representation of two-layer circulation in an atoll lagoon. White arrows represent surface currents, blue arrows are deep counter currents, and black arrows are tidal currents concentrated in the tidal passes. (b) This cross-sectional view of the atoll lagoon along line A–A' in panel A shows the surface current (white arrows) forced by wave-driven cross-reef flow plus wind stress and a counter current in the deep part of the lagoon.

time of 2–5 days. Wave- and tide-driven flows through shallow reef channels were important to ocean–lagoon exchange, but along with wind were found to be less important than tidal exchange as a driver of lagoon circulation. In the case of atoll-like platform reefs, such as One Tree Reef of the Southern Great Barrier Reef, lagoon water may be ponded behind the high rims of the platform and may be largely isolated from oceanic energy (tides and waves) that drives circulation in most reef lagoons (Ludington, 1979; Frith and Mason, 1986).

### Summary

Coral reef lagoons span a wide spectrum from small nearly closed to large and open lagoons in atolls. Water circulation in these lagoons results from the strength and duration of driving forces (e.g., wind speed and direction, wave-swell height and direction, tides, major currents, and salinity and water temperature variations) and their interaction with the morphology and geometry of the lagoon. In small nearly closed lagoons, currents are directed nearly parallel to the coastline because of the morphological and geometric constraints under the action of waves, tides, and winds.

As the size and openness of the lagoon increases, winds and tides become the dominant forces of water circulation. In large lagoons of atolls, winds and tides are the primary forces of circulation assisted by the wave driven across the reef flux. However, because these lagoons are much deeper, water stratification becomes relevant and two-layer flows are common.

## LAGOONS

David Hopley  
 James Cook University, Townsville, QLD, Australia

Fully or partly enclosed depressions in coral reefs are common. They range in depth from 1 or 2 m to > 90 m with the largest occurring in atolls, e.g., Kwajalein (Marshall Islands) 120 × 32 km or Rangiroa (Tuamotu) 79 × 34 km. They have many origins including the following:

- Shallow moats behind reef flat rubble banks
- “Boat channels” a few metres deep behind a fringing reef attached to the shore
- Deeper lagoons behind reefal rims around volcanic islands as in the Darwinian sequence
- Shelf reef lagoons of probable karst inheritance (Purdy, 1974) but with some Holocene growth to the rim (see *Reef Classification by Hopley (1982)*). These reefs and their lagoons can be > 100 km<sup>2</sup> in area (e.g., Hopley, 2006)
- Extensive lagoons of atolls some of which may be entirely closed off from the ocean. Purdy and Winterer (2001) have shown that only about 10 m of lagoon rim relief in these largest of lagoons (> 250 km<sup>2</sup>) is the result of reef growth, the remainder (> 20 m) is due to dissolution over several glacial/interglacial cycles and only a small amount due to subsidence
- Depressions resembling karst but originating from the rapid *Acropora* dominated growth (> 6 m/ka) from patch and reticulated foundations and including collapse of depression walls (Wyrwoll et al., 2006)

All types are sediment sinks and for fringing reefs terrigenous sediments may dominate the lagoon floor. In terms of

hydrography, lagoons can be divided into three classes, normal, brackish, and hypersaline, which combined with circulation, can exert a major influence on the sedimentological characteristics of the lagoon (Milliman, 1974). Normal lagoons display temperatures and salinities similar to those of the adjacent ocean. In brackish lagoons, freshwater influx from run-off and rainfall exceeds evaporation: the opposite is true of hypersaline lagoons.

Away from the land masses, lagoon sediments are totally calcareous (apart from a few diatoms and sponge spicules). Corals are common throughout apart from that in deeper lagoons below the level of coral and algal growth where black muds may dominate. Calcareous algae and shell fragments from gastropods, echinoderms, crustaceans, etc. may also be found in all parts of the lagoon but foraminifera tend to dominate shallow waters and *Halimeda* deeper zones beyond 50 m (Guilcher, 1988).

Studies of lagoon infill (e.g., Davies and Hopley, 1983; Purdy and Gischler, 2005) show that once reefs reached sea level at the end of the Holocene transgression, lateral movement of sediment becomes a dominant process, with infill rates of up to 8 m/ka. Occasional high energy storms produce rates up to 18 m/ka. Lagoons in smaller platform reefs may have totally infilled during the Holocene (Hopley et al., 2007). However, as Purdy and Gischler (2005) have shown for large atoll scale lagoons, the extent of Holocene high stand lagoon filling may be minimal. Lateral infilling also comes from patch reef growth, the modal rate of which may be 8 m/ka which once the reef is at sea level also reverts into lagoon infilling in the form of a sediment halo around the patch reef. Although, current speeds, within lagoons are normally low, some sediment movement may take place with the help of bioturbation (Frith, 1983).

## LAST GLACIAL INTERSTADIALS

Yusuke Yokoyama  
 The University of Tokyo, Chiba, Japan

## Definition

Relatively warm periods recorded in Greenland ice cores during the last glacial.

Last glacial interstadials are strongly related to ocean circulation changes resulting from partial collapsing of continental ice. Sea-level changes also occurred. Ice cores obtained from deep drilling in Greenland by international collaborative efforts have revealed a detailed history of paleoclimates. One of the important discoveries from the ice cores was the identification of abrupt shifts in climate, in particular during the last glacial. Shifts in Greenland surface-air temperature were abrupt changing from cold status to warm status by as much as 10–15°C in decadal time scales or less. This had been previously found in the interval between 20,000 and 75,000 years ago (e.g., Dansgaard et al., 1982; Johnsen et al., 1972, 1992). In the meantime, deep-sea cores were also analyzed and indicated similar millennial scale oscillations. There are two types of rapid climate change according to detailed examinations of the ice and marine cores, namely Dansgaard-Oeschger (D–O) events and Heinrich events (HE). The former has approximately 1,500 year cycles (e.g., NGRIP Members, 2004) whereas the latter appeared every ca. 7,000 years (Yokoyama et al., 2001a; Clark et al., 2007). HE were discovered from sedimentological analyses in the North Atlantic as was noted from the synchronous

appearance of ice rafted detritus (IRD) from deep-sea cores (Heinrich, 1988). This had been recurring when the Greenland surface temperature was at its coldest (Alley, 1998). Distribution patterns of the ice rafted detritus (IRD) in the cores indicated that the Laurentide ice sheet and the ice sheets around the Nordic Seas are the main contributors for releasing icebergs (Heinrich, 1988; Bond et al., 1993; Bond and Lotti, 1995; Hemming, 2004), which melted around 45 degrees north to release freshwater. This impacted on the intensity of Atlantic Meridional Overturning Circulation (AMOC) through the decrease of the North Atlantic Deep Water (NADW) formation. Several paleoceanographic studies showed that the AMOC during a HE nearly ceased and cold climate resulted in the North Atlantic region as was followed by rapid warm D–O interstadials found in Greenland ice cores. During a cold D–O stadial, most of the northern Hemisphere experienced cold climate conditions. The magnitude of sea-level rise associated with each HE has been estimated from 10 to 30 m (Yokoyama et al., 2001a, b; Siddall et al., 2003) and the style of reef development was unique (“pack-up”; Esat and Yokoyama, 2006) compared with traditional three types categorized as “keep-up,” “catch-up,” and “give-up” types depending on the corresponding sea-level changes (Neuman and Macintyre, 1985). The strength of AMOC during a HE was clearly recorded as levels of radiocarbon in corals (Yokoyama et al., 2000, 2001a, 2008). Therefore, frequent but less extensive ice sheet collapses have been repeated and was probably triggering the reduction of NADW formations, but AMOC would still have operated (Ganopolski and Rahmstorf, 2001). The inception and propagation of HEs have been proposed previously (e.g., Hemming, 2004; Clark et al., 2007) including internal oscillations of ice sheet (MacAyeal, 1993; Papa et al., 2006), growth and decay of ice shelf (Hulbe et al., 2004; Alley et al., 2006), and oceanic system dictating mechanisms (Flückiger et al., 2006). Whatever, the key region for creating these abrupt climate changes is the North Atlantic cryosphere-ocean system. Coral reef development during last glacial interstadials and stadials is reported from rapidly uplifted regions such as the Huon Peninsula, Papua New Guinea (Yokoyama et al., 2001; Chappell et al., 1996), and Vanuatu (Cabioch and Ayliffe, 2001).

### Definition

Occurred at the Last Glacial Maximum (19,000–30,000 years ago) when sea level was lowered globally to as much as 120–130 m.

Last Glacial Maximum (LGM) is the time when global temperature was significantly lower than that of the present and ice sheets covered large areas of northern hemisphere continents. The conventional definition of the LGM was made by an international research project group in the 1980s (e.g., CLIMAP Project Members, 1981) as was the time when low-latitude ocean temperature was at its minimum. However, recent advances of paleoclimate study show that the timing of the LGM is varied depending on the locations on the Earth's surface. Therefore, the most recent date of the “global” LGM is defined as the time when the global ice volume was at its maximum and sea level was at its lowest (Mix et al., 2001). There had been various estimates of the exact levels of sea-level lowstand. Nakada and Lambeck (1988) and Fleming et al. (1998) reviewed published sea-level observations obtained from the sites far from former ice-covered regions. They conducted corrections of glacio-hydro-isostatic adjustments of solid earth (GIA) and concluded that the LGM sea level was 125–130 m lower than the present. Corals obtained from Barbados provided the last 18,000 years of sea-level record and it led to the conclusion that this level may have been 120 m lower than

the present (Fairbanks, 1989; Bard et al., 1990). On the other hand, others claimed that the LGM level may have been only ~105 m (Peltier, 1994). Thus there were large discrepancies for estimates of the sea level at the lowstand during the last glacial.

The Australian continental shelf was targeted to tackle this problem since it is located far from formerly glaciated regions, hence expected GIA is minimal and those corrections are not sensitive to the ice-loading geometry. The continental margins are tectonically stable as was supported by the elevation of the last interglacial shorelines close to the present day sea level (Marshall and Thom, 1976; Stirling et al., 1998). Ferland et al. (1995) worked off Sydney using vibro-cores and concluded that the shelf was exposed during the last glacial lowstand shallower than –130 m. The high-energy sedimentary environments prohibited further refinements. The north-western shelf of Australia, on the other hand, is suited for studying sea-level lowstand since the area is characterized by shallow and wide depressions and hence the conditions may have been favorable for the preservation of former sea-level indicators (van Andel and Veevers, 1967; Yokoyama et al., 2000, 2001a). A series of gravity and vibro-cores were recovered and micropaleontological study with detailed radiocarbon dating shows that the LGM sea level locally reached at 125+/-4 m at least between 22,000 and 19,000 years B.P. and the LGM was terminated rapidly 19,000 years ago when approximately 10% of ice volume decreased. This probably created a ca. 10–15 m rise in sea level (Yokoyama et al., 2000, 2001a). Local sea-level lowstands can be translated into the so-called ice volume equivalent sea level, as much as 135 m (Yokoyama et al., 2000; Lambeck et al., 2002), which can be obtained after GIA corrections. This was the first observation, which extended back into the middle of the LGM, and the GIA-corrected Barbados record was consistent with the northwestern shelf result (Yokoyama et al., 2000). This quantity was further supported by independent studies such as detailed microfossil examinations (De Deckker and Yokoyama, 2009), GIA model (Milne et al., 2002; Mitrovica, 2003), and the Sunda Shelf record (Hanebuth et al., 2000, 2009). Predicted relative sea-level values are available around the Australian continent (Yokoyama et al., 2001b) and the model predictions are confirmed from occurrence of ooids from the Great Barrier Reef, where this part of the shelf was also exposed during the lowstand (Yokoyama et al., 2006). Various impacts from such a lowstand on coral reef formations are still under debate, since there are only a few LGM coral observations so far reported. Coral samples obtained from deep-sea drilling currently being undertaken will allow us to understand the mechanisms on this topic.

## Introduction

The last Interglaciation (LIG), defined by half-peak heights in the marine oxygen isotope record, is centered around 125 ka ago and was the last time global ice-volume was at a minimum and sea levels were higher than present (Martinson et al., 1987). The highstand of sea level (SL), which occurred within the LIG, correlates with marine isotope stage (MIS) 5e and overlaps with warm terrestrial stages such as the Eemian, Sangamonian, and Ipswichian (Shackleton et al., 2003). The precise timing of the highstand is based on radiometric dating of SL indicators such as fossil-reef corals and speleothems in stable areas, but there is still uncertainty regarding the reliability of its bounding ages (Edwards et al., 1987; Chen et al., 1991; Szabo et al., 1994; Stirling et al., 1998; Esat et al., 1999; but see Cheng et al., 2009).

In terms of climate, the LIG highstand was a time of unprecedented warmth which led to significant northward expansion of temperate biota. Animals such as hippopotamus were recorded in central and northern Europe for the first and perhaps only time in the last 500 ka (e.g., Schreve, 2009). These dramatic shifts in biota largely resulted from the polar amplification of warming. In the Northern Hemisphere, average summer insolation was 11% above the present between 130 and 127 ka (CAPE, 2006). This led to a rapid, early deglaciation and intensification of Atlantic meridional overturning circulation, which combined to melt sea-ice, permafrost, and almost all glaciers, allowing a vast expansion of the boreal forest to the shores of the Arctic Ocean (CAPE, 2006). The positive feedback resulting from vegetation-induced changes in albedo amplified Arctic summer temperatures, which climbed to an average of 5° above the present (Chapin et al., 2005). Such high temperatures led to the complete disappearance of the south dome of the Greenland ice sheet and to a loss of almost half of its present-day volume, leading to significantly higher SL (Cuffey and Marshall, 2000; Otto-Bliesner et al., 2006).

These elevated temperatures, together with the smaller latitudinal temperature gradient, also led to more

widespread reef development than present, and reefs not only extended further into coastal lowlands but significantly expanded their latitudinal range (Kendrick et al., 1991; Greenstein and Pandolfi, 2008; McCulloch and Mortimer, 2008). The elevation and age of fossil reef-crests from tectonically stable terrains in several areas of the world indicate that the sea level was 3 m higher than the present by ~125 ka and peaked at 6 m sometime thereafter (Stirling et al., 1998; Blanchon et al., 2009).

Reef development during the LIG has played a particularly important role in understanding the causes of climate and sea-level oscillations during glacial–interglacial cycles. First, the absolute timing and duration of reef development has been used to test the Milankovitch theory of orbital forcing, which holds that variation in northern-hemisphere summer insolation drives ice-sheet growth and decay as reflected in SL records (Hays et al., 1976). Second, the age and elevation of fossil reef-crests allow the reconstruction of a high-resolution record of ice-volume and sea level during the highstand, and thus provides an analog for ice-sheet stability in the present interglacial under sustained, greenhouse-gas induced global warming.

### Reef development in uplifted terrains

Reef development in uplifted areas can potentially provide an assessment of the timing of postglacial sea-level rise (or glacial termination) and the duration of the interglacial but, due to the tectonic overprint and the possibility of coseismic displacement, it is difficult to infer anything about the detailed SL behavior or the absolute elevation reached during the highstand.

### Barbados

Pleistocene reef terraces on Barbados have been extensively dated by various methods since the late 1960s, and 15 separate terraces have been identified which represent an episodic record of reef development from 640 to 60 ka (Broecker et al., 1968; Meselella et al., 1969; James et al., 1971; Matthews, 1973; Bender et al., 1979). The continuous uplift of the island at rates of up to 0.53 mm/year has produced terraces that record the last six or seven interglacial SL highstands, corresponding to MIS 5–17 (Shackleton and Matthews, 1977; Fairbanks and Matthews, 1978; Taylor and Mann, 1991; Speed and Cheng, 2004).

Early reconnaissance mapping by Meselella and coworkers discovered that many of the interglacial terraces on Barbados displayed a regular, depth-related facies sequence consisting of a deep head-coral zone which passed vertically into thickets of branching *Acropora cervicornis*, and then into the more robust *A. palmata* in the reef-crest zone (Meselella, 1968; Meselella et al., 1970). As seen in Figure 1, the elevations of these coral assemblages on the terrace surfaces are very similar to the depth-zonation on mid-twentieth century Jamaican reefs (Meselella, 1967). In his analysis of the terraces,

Meselella also observed reefs with two main types of facies sequences: those with over-thickened reef-crest units, and those with a shallowing-up sequence which started in deep head corals and finished in reef-crest or rear-zone facies (Meselella et al., 1970). The first sequence he attributed to a keep-up response to rising SL, and the second to a prograding response to a semi-stable SL. Based on known rates of SL rise, uplift, and reef growth, he speculated that reefs did not initiate on Barbados until later stages of the transgression, when the rise slowed and approximated accretion rates of the reefs (see Meselella et al., 1970, Fig. 16). He postulated that this late transgressive stage of reef development was initially characterized by vertical accretion of facies producing an over-thickened sequence, and then to progradation as relative stillstand conditions prevailed.

The fundamental problem with this keep-up and prograde model was that Meselella was uncertain as to what facies lay at the base of the terraces because shallow road-cuts provided no exposure. He postulated that reef bases may have started either as a pioneering assemblage of deep-water corals that built up into a climax reef-crest community, or initiated with a full zonation that responded directly to SL rise. Furthermore, he acknowledged that his model could not account for certain morphological anomalies in the LIG reef terrace. For example, a reef terrace on the south coast is split into two sub-terraces which are both rimmed by facies containing the reef-crest coral *A. palmata* (Figure 1). Subsequently, Ku et al. (1990) interpreted the lower terrace, informally known as the “Maxwell Hill” sub-terrace, as a reef-crest-lagoon unit and suggested that this division might represent stratigraphic evidence of a double highstand (Figure 1). Upon dating, however, he could not detect any significant age difference between the two sub-terraces. More recently, Schellmann and Radtke (2004) redated these two sub-terraces using electron spin resonance and claimed significant age differences between terraces, with the upper terrace being older (128 ka) than the lower (118 ka).

Unfortunately, there are problems with the analysis of Schellmann and Radtke (2004). First, the terrace ages have analytical errors as large as their age differences, and the age ranges for each terrace overlap to such an extent that the new age designations are effectively meaningless. Second, no facies analysis of the lower sub-terrace was presented to support the claim that it was a reef-crest-lagoon system (as suggested by Ku et al. [1990]). And third, it ignored a detailed facies analysis by Blanchon and Eisenhauer (2001), which confirmed that a true reef-crest facies was absent from the lower Maxwell Hill subterrace (Figure 1). In fact, these new facies data showed that the two sub-terraces combined have a facies zonation that is consistent with a single-reef system, with the upper sub-terrace encompassing the rear zone and a high-energy reef-crest facies, and the lower sub-terrace the reef-front *A. cervicornis* facies and a peripheral ridge of inter-grown thickets of *A. palmata* and *A. cervicornis* (Blanchon and Eisenhauer, 2001). That *A. palmata* is

**Last Interglacial and Reef Development, Figure 1** Stratigraphy and architecture of the uplifted LIG reef terrace around Barbados compared to the same scale with modern-reef architecture from the north coast of Jamaica (ca. 1950). Comparison of coral depth-zonation from the modern reef, with the surface-facies depth-zonation from the reef terrace, shows a concordant depth-zonation. This concordance facilitates a reconstruction of the fossil-reef response to SL rise, and shows that along the south coast of the island, LIG reefs had a vertical or prograding keep-up architecture. Along less-exposed sections on this coast, the reef developed two sub-terraces and a sill reef. Note also an intertidal notch at ~3 m above terrace surface at Gibbons. Along the west coast of the island, the reef terrace developed a retrograding keep-up architecture. These different variants of keep-up architecture are a response to weaker wave-fields along the protected west coast.

inter-grown with the fragile-branching *A. cervicornis* in these thickets, and that neither are coated with shallow encrusters, indicates that the peripheral ridge was a submerged shelf-edge feature, not a reef-crest. This is also supported by the fact that ridge development is restricted to exposed east-facing sections of the sub-terrace where higher wave-energy would have encouraged deeper *A. palmata* development seaward of the crest. Similar ridges, known as sill- or shelf-edge reefs, are common in the Caribbean and have been reported rimming the north coast of Jamaica, the western shelf of Barbados, the Belize Barrier Reef, and the island of Grand Caymen (Goreau and Goreau, 1973; Rützler and Macintyre, 1982; Macintyre et al., 1991; Blanchon and Jones, 1997).

Apart from resolving morphological complications, Mesolella's keep-up and prograde model has also been reevaluated by Speed and Cheng (2004), who reported an unusually deep road-cut on the west coast that exposed the terrace base (Figure 2). That section showed a thin

basal unit of *A. palmata* clasts, in-place head corals, and *A. cervicornis*, rising 20 m laterally upslope beneath a thick reef-front unit of *A. cervicornis*. The basal unit was interpreted by Speed and Cheng (2004) to be a low-energy fringe reef which kept up with SL rise and produced a retrogressive and diachronous layer that was progressively buried by an *A. cervicornis* facies forming seaward in deeper water. This section therefore provided an answer to Mesolella's dilemma, and proved that reefs did not progress from deep-water pioneer into a shallow climax communities as they caught up with SL, but initiated as fully zoned reefs that responded directly to SL rise, producing a clear keep-up response.

The new retrogressive keep-up model of west-coast terraces was inferred by Speed and Cheng (2004) to exist widely in other Barbadian terraces. But it is unclear how applicable their model is to terraces on the southeast coast, which developed under higher-energy wave-fields and developed more extensive reef-crests with significant

**Last Interglacial and Reef Development, Figure 2** Stratigraphy and architecture of the uplifted LIG reef terrace along the Huon Peninsula compared at the same scale to local modern-reef architecture (strictly reliable ages shown in *bold*). Note that like its modern counterpart, the fossil terrace has an inner-fringe reef and an outer-barrier reef, but they are at different elevations implying that the terrace is tilted and/or has been substantially eroded. The latter process would also account for the narrowness of the fossil barrier reef compared to the modern. Compared to the modern architecture, vertical sections from the LIG terrace show expanded facies depth-zones, with mid- and shallow-slope assemblages being as much as 20 m thick compared to 5 m in modern. This implies that they kept up with rising SL during the penultimate deglaciation. These sections do not represent the entire sequence, however, which is as much as 90 m thick and at least one shallow-water unit has been identified at the base of the reef-front slope (in Aladdin's Cave). This is clearly inconsistent with continuous reef development which should, as seen from the modern architecture, produce a simple shallowing-up facies sequence if the reef had a prograde keep-up architecture.

topographic relief (Figure 1). From this area, for example, Blanchon and Eisenhauer (2001) reported a 17 m thick reef-crest section composed of in-place *A. palmata* colonies and their boulder-sized fragments, topped by a 3 m back-reef unit dominated by diverse branching corals (Figure 1). They interpreted this section to represent a keep-up reef which initially aggraded vertically in response to a SL rise of between 14 and 20 m, and later

underwent progradation to produce a cap of back-reef facies. As a consequence, Mesolella's keep-up and prograde model may better represent terrace architecture along the southeast coast, whereas Speed and Cheng's retrogressive keep-up model better represents west-coast terraces. However, exclusive application of either model to Barbadian reef terraces clearly underestimates the role of wave-energy in shaping reef architecture (Yamano et al., 2003).

Recent refinement in the precision of U-series dating has encouraged several attempts to date the early stages of reef development exposed in these deep sections. Dates from the 17 m thick reef-crest section from the southeast coast reported by Blanchon and Eisenhauer (2001) were affected by diagenesis, and even those with reliable isotopic signatures showed no stratigraphic consistency. In the middle of the unit, a single, strictly reliable age of 129 ka suggested a significant part of the reefs development predated the insolation maximum. But absence of replicate ages from this sample means that true-age variation and hence the samples reliability cannot be verified. A further attempt was made by Gallup et al. (2002), who dated samples from the deep west-coast road-cut using both  $^{230}\text{Th}$  and  $^{231}\text{Pa}$  isotopes. Although these two chronometers have similar chemical affinities and the same uranium parent isotope, they provide an independent check on true-age variation of the sample (Edwards et al., 1997). A single, isotopically pristine coral from the base of the terrace gave concordant ages of 136 ka, indicating that it grew during the penultimate deglaciation at an equivalent depth of 18 m below present SL (Gallup et al., 2002). If this age is accurate, it implies that SL had completed 80% of its rise prior to the insolation maximum, indicating that other factors besides orbital forcing may have been involved in this early deglaciation. Samples from a lower unit also gave concordant ages of 129 ka implying that the SL rise was interrupted by a reversal before attaining its highstand. Subsequent work by Speed and Cheng (2004), however, demonstrated that corals in this lower unit were detrital and thus have no significance for SL. In addition, more precise ages from speleothems indicate that glacial termination II started at 129 ka (Chen et al., 2009), casting doubt on claims of early reef development and the  $^{231}\text{Pa}$  method of age verification.

### Huon Peninsula, Papua New Guinea

The age and elevation of uplifted flights of reef terraces on the Huon Peninsula have also been the subject of extensive study and used to corroborate the SL change and ice-volume over the last glacial cycle (Chappell, 1974, 2002; Aharon and Chappell, 1986; Chappell and Shackleton, 1986; Stein et al., 1993; Esat et al., 1999). Although it is clear that the age of successive terraces increase upslope, and that they consist of shallow-water corals, the fundamental basis of SL reconstructions from individual terraces is their comparison with the depth-zonation and architecture of local modern and Holocene reefs. Unfortunately, little is known about these reefs or their development (Edinger et al., 2001). As summarized in Figure 2, basic descriptions of local reefs have been reported by Chappell (1974) and Nakamori et al. (1994) who indicate that they consist of a fringing and barrier-reef complex separated by a narrow sediment-dominated lagoon. Although not present in the lagoon, a depth-zonation based largely on the presence of coralline algal

crusts and coral morphology has also been reported from the barrier crest down the seaward slope by Nakamori et al. (1994) and Matsuda et al. (1994).

A quantitative analysis of coral assemblages on the crests and slopes of the Pleistocene terraces found that, although zonation of assemblages generally reflected the modern zonation, it could only be reliably differentiated using the presence or absence of thick crusts of coralline algae (Pandolfi, 1996). In most sections, coral communities shared more than half of their common species, and in places zonation was almost indistinguishable. The only indicator was the greater occurrence of *Fungia* spp. and Favid head corals in the lower-slope zones. Additional differences between the modern and fossil communities was that fragile-branching corals were underrepresented in slope sections and some exclusively upper-slope corals on modern reefs, such as *A. gemmifera*, were also common in the deep slope assemblage of the fossil reefs, indicating down-slope transport (cf. Van Woesik et al., 1991).

For the LIG terrace in particular, measured sections at several locations show that reefal zonation is similar to the Holocene, consisting of a fringing reef, a lagoon, and a barrier-reef complex (Chappell, 1974; Aharon and Chappell, 1986; Pandolfi and Chappell, 1994). But these sections also show that individual reef zones are much thicker than in the modern-reef zonation, indicating that the LIG reef complex likely responded to rising SL (Figure 2). A similar response was identified from the Holocene reef complex itself, where a 52 m over-thickened reef unit was recovered from a bore-hole on the barrier crest (Chappell and Polach, 1991). Dating of corals in this core showed that reef development initiated 13 ka ago but ceased by 6 ka due to uplift (Chappell and Polach, 1991; Edwards et al., 1993; Ota and Chappell, 1999). On the basis of these data, several workers have proposed that reef development during the LIG and Holocene had a simple progradational architecture with the barrier crest keeping pace with SL rise and migrating over its seaward slope (Chappell, 1974, 1980; Chappell and Veeh, 1978; Chappell and Polach, 1991; Ota and Chappell, 1999). Yet this keep-up model is not adequately supported by the data, given that neither coral zonation nor facies geometries have been fully established for either the LIG or Holocene reef complexes. It could be, for example, that reefs did not always maintain their position at SL, and may have been outpaced by meltwater pulses.

In fact, investigation of the LIG terrace has found that a simple keep-up reef architecture is difficult to reconcile with the actual stratigraphy, which apparently shows significant complexity (Stein et al., 1993; Esat et al., 1999). For example, between the Kwangam Gorge and the slopes above the villages of Sialum and Kwambu, there are several well-studied sections through the fringing, lagoon, and barrier-reef complex (Figure 2). These sections show that the outer barrier (terrace VIIb) forms a narrow ridge with local reef-crest remnants (Stein et al., 1993). Its seaward face exposes coral and *Halimeda* gravels with

patches of deep-water coral further down-slope. Behind the barrier, the lagoon is dominated by skeletal sand interspersed by patch reefs, and passes laterally into coral thickets of the fringing reef (terrace VIIa). This double-reef complex is dissected by the Kwangam Gorge, where the fringing reef is seen to pass beneath the lagoon floor into the barrier (Bloom et al., 1974). The gorge also exposes an erosion surface ~20 m below the barrier crest sloping gently for some 30 m into the lagoon, but it shows no evidence of subaerial exposure (Stein et al., 1993). Although laterally discontinuous, this erosion surface was interpreted as separating the two reef units and indicating that the barrier reef disconformably overlies the fringing-reef unit (Chappell and Veeh, 1978). Part of this interpretation was clearly based on different alpha spectrometric U-series ages that were reported early on from the two reef-crests by Veeh and Chappell (1970) and Bloom et al. (1974). But recent dating using more precise and better screened U-series ages has failed to replicate these early results, and has also identified significant age inversions down the barrier-reef slope where no evidence of stratigraphic discontinuity exists (Stein et al., 1993).

A similar erosion surface was observed to divide reef units in the Sazum River gorge, a further 10 km to the northwest (Aharon et al., 1980; Aharon and Chappell, 1986). At this location, a 30 m barrier-reef section erosively overlies a 70 m thick reefal unit that was implicitly assumed to be a seaward extension of the fringing-reef unit (Figure 2). However, this underlying reefal unit was also encountered in "Aladdin's Cave" located some 90 m below the barrier crest close to the Kwangam gorge (Esat et al., 1999). A shallow head-coral assemblage found in the walls and floor of the cave imply that this underlying reef unit is an early transgressive reef that accreted vertically in response to the deglacial SL rise, as has also been illustrated for the Holocene reef terrace (Chappell and Polach, 1991; Ota and Chappell, 1999). Corals from this cave returned seven isotopically acceptable  $^{230}\text{Th}$  ages of between 125.6 and 133.7 ka (i.e., a 7.2 ka true-age variation). These were averaged by Esat et al. (1999) to assign an age of 130 ka to the cave reef (ignoring a reliable age of 115 ka), and then compared to an average of 134 ka assigned to the barrier crest from four corals dated by Stein et al. (1993), (again ignoring four significantly younger ages also reported by those authors). By comparing the average age and elevation of these two coral groups, Esat et al. (1999) claimed that SL fell rapidly, at least 70 m from the 134 ka barrier-crest group to the cave group, and then rose rapidly, at least 85 m from the 130 ka cave group, with both the fall and the rise occurring within the 4 ka difference between groups. Unfortunately, the validity of this comparison is questionable given that it ignores younger ages from the cave site as well as those from the barrier-crest site reported by Stein et al. (1993). It is much more likely that these stratigraphic age inversions reflect true-age variability (Scholz and Mangini, 2007) and that the cave is simply the oldest part of terrace VII which accreted vertically as SL rose.

It is clear from the foregoing, that the interpretation of LIG reef architecture in the Huon Peninsula has been obfuscated by various attempts to obtain a terrace chronology. The fundamental problem has been that unreliable U-series age determinations, which clearly fail any test of stratigraphic consistency, have driven the analysis of the stratigraphy itself, rather than the other way round. This has led to disconformities being inferred between stratigraphically inverted ages, or inverted ages simply being ignored, rather than acknowledging that many dates have large true-age variabilities and that more than 50% of those with "reliable" isotopic signatures have discordant  $^{231}\text{Pa}$  ages (Scholz and Mangini, 2007). As a result, SL histories determined from these inadequate data are premature, especially interpretations of extreme excursions based on ages alone (Esat et al., 1999).

Furthermore, and as noted by Pandolfi and Chappell (1994, p. 138), widely spaced stratigraphic sections are merely "one-dimensional sloping profiles of three-dimensional reef structures" and say little about stratigraphic architecture, which has been poorly documented in the area. And what little stratigraphic detail has emerged has been over-interpreted. Erosion surfaces which lack evidence of subaerial exposure are clearly difficult to interpret in the absence of supportive contextual data, given that they can be produced by processes other than SL fall. Likewise, it is premature to apply a keep-up model of interglacial reef development in the absence of internal facies geometries from either the LIG or Holocene terraces. Even the Holocene reef structure, which has been described from a long bore-hole (Chappell and Polach, 1991), lacks a taxonomy to species level and thus identification of coral zonation (biofacies) data, making interpretation of SL history or reef response difficult to substantiate (cf. Chappell and Polach, 1976).

## Red Sea

The Red Sea is an active continental rift system related to the development of a spreading center between the African and Arabian plate. Dynamic interplay between rift tectonics, halokinetic faulting, volcanism, climate, and SL variation during the Quaternary has produced a complex stratigraphy where abrupt facies changes between river alluvium, alluvial fans, reef, lagoon, Salina, and beach units, make it difficult to correlate between areas and unequivocally separate tectonic from eustatic SL events (Plaziat et al., 1995). This complexity, together with incomplete exposure and limited uplift of LIG deposits, makes it a difficult area to investigate either interglacial duration or highstand character. Nevertheless, several investigations of reef development during the LIG have been reported from the Egyptian and Eritrean coasts of the Red Sea.

Along the coast of Eritrea, an uplifted and tilted LIG reef sequence near Abdur shows two main stages of shallow-reef development (Walter et al., 2000; Bruggemann et al., 2004). The lower unit is composed of fringing-reef

tract with extensive sandy lagoonal and scattered patch reefs. The reef-crest facies consists of dense thickets of *Goniopora* sp. and *Stylophora pistillata* and forms a shallowing-up sequence, indicating seaward progradation. The lower unit is truncated by an intermittent marine-erosion surface that shows evidence of being both bioeroded and burrowed suggesting that in some areas the surface was a firm ground and not completely cemented. This surface is directly overlain by a second but more limited fringing-reef tract consisting predominantly of reef-crest and reef-front units with a diverse assemblage of in-place corals (Bruggemann et al., 2004).

These two superimposed reef tracts therefore have a back-stepping architecture, which implies that the first stage of reef development was abruptly terminated and was followed by the relocation and reinitiation of the second reef-crest further inland over the former lagoon. Bruggemann et al. (2004) interpreted this reef demise and relocation to have resulted from a brief eustatic SL fall, but could not find any evidence of subaerial exposure associated with the marine-erosion surface. The discontinuous nature of the erosion surface, and the fact that the surface was not completely cemented, is inconsistent with SL fall, and in fact suggests the opposite scenario whereby reef back-stepping may have been the result of a rapid rise of relative SL. Whatever the interpretation, however, the neotectonic setting of the site means that the possibility that coseismic displacement was the cause of reef back-stepping cannot be discounted.

Along the Egyptian coast, in the northern Red Sea, two episodes of deposition during the LIG have been described by Plaziat and others (Plaziat et al., 1998a, b; Orszag-Sperber et al., 2001). During the first stage, fringing-reef tracts topped by beach gravels developed along the coast at elevations between +5 and 10 m. This stage was followed by a down-cutting erosive event that excavated small basins behind breaks in the reef crest. The first depositional event in these depressions was a thin sequence of open-marine sediments containing molluscs and in-place corals. This was followed by a thicker sequence of laminated subaqueous gypsum topped by tepees that reached an elevation of ~3 m below the reef-crest. The final filling unit consisted of massive gypsum consistent with an emergent sabkha environment.

This unusual sedimentary sequence was interpreted to result from a rapid SL fall of ~10 m which caused the excavation of the back-reef depressions (Orszag-Sperber et al., 2001). The subsequent rise of SL back to the same level as before (within 1–3 m) led to the filling of the depressions. The abrupt transition from an open marine to restricted deposits in this fill-sequence was postulated to result from a brief pluvial episode that increased input of sediment to the coast and occluded the gap in the fringing-reef unit, thus sealing the depressions off from the marine environment (Plaziat et al., 1998a; Orszag-Sperber et al., 2001). However, other interpretations are also consistent with these stratigraphic data. For example, down-cutting could result from a rapid SL rise and

reworking of back-reef deposits during storms and sediment export through the reef gaps. These open-marine conditions would favor the initial deposition of open-marine faunas and the abrupt change to restricted environments would mark the start of SL fall at the end of the LIG. That no deepening of these depressions occurred during the ensuing glacial fall in SL, lends support to this latter interpretation. However, confirmation of either interpretation requires a precise chronological framework which is still lacking in this region.

### Reef development in more stable terrains

Reef development in stable sites can provide a detailed look into the timing and duration of peak interglacial conditions during the highstand, as well as the absolute elevation and SL behavior during that highstand. Detailed descriptions of LIG reefs in stable areas have traditionally concentrated along the southern passive margin of the North-American Plate, including sites in Florida, the Bahamas, the Caymans, and the Yucatan. But recent work has also been reported along the Western Australian passive margin of the Indo-Australian Plate from Cape Range to Cape Leeuwin. This facilitates a comparison of reef development within each region and between regions themselves.

#### Florida

Pleistocene reef development in Florida's Key Largo Limestone was described as early as the late eighteenth century (Agassiz, 1896), but it was not until the mid-1960s that U-series dating proved that those elevated reef deposits were of LIG age (Broecker and Thurber, 1965; Osmond et al., 1965). As its name suggests, the reefal Key Largo Limestone is best developed along Key Largo and Windley Key where it forms a broad ridge that rises to a level of +3 m (Harrison and Coniglio, 1985). Although widely cited to reach 5.5 m above mean SL, the original description states that it has an average elevation of +1 m "with local prominences which in two places reach a maximum height of 18 ft" (5.5 m) (Hoffmeister and Multer, 1964, p. 355). At the type locality on Windley Key, the reef unit covers an older topographic high at +1 m, and forms a 2 m thick layer of coalesced patch reefs formed of head corals, particularly *Montastrea annularis*, interspersed with thickets of *A. cervicornis* and small branched *Porites* (Stanley, 1966). The matrix is a skeletal sand composed of mostly *Halimeda* and mollusc fragments. The reef unit gradually dips away from this topographic high and, at its northern and southern outcrop limits, is overlain by or grades into the oolitic sands of the Miami Limestone (Multer et al., 2002). These oolitic units have developed shorelines consistent with a +6 m SL highstand at both Key West in the south and Palm Beach in the north (Hoffmeister and Multer, 1968; Perkins, 1977; Multer et al., 2002). The absence of ooids in the reef matrix and the fact that the reef unit underlies these oolitic sand bodies indicates that reef development likely

preceded the oolite shoreline development during the +6 m highstand (Harrison and Coniglio, 1985). Unfortunately, more precise U-series mass spectrometric dating has been unable to confirm the exact stratigraphic relation between the reef and oolite units due to the impact of diagenesis (Fruijtier et al., 2000), and only one age of 128.1 ka with a strictly reliable isotopic signature has been returned from the reef unit (Multer et al., 2002).

In the absence of reliable ages, the interpretation of reef development in the Key Largo Limestone has focused primarily on the paleo-water depth in which the corals grew. The problem was the lack of evidence for coral zonation or the presence of the reef-crest coral *A. palmata* which might confirm a shallow-water origin. As a result, early interpretations suggested water depths exceeded 6 to 12 m (Stanley, 1966). This was later discounted by evidence of +6 m shoreline development in the oolitic sand bodies (Hoffmeister and Multer, 1968; Perkins, 1977; Harrison and Coniglio, 1985; Multer et al., 2002). All later interpretations therefore favored a shallow, protected, patch-reef setting, but differed according to what afforded that protection. Notions of a reef-crest barrier were finally discounted by drilling data which failed to encounter reef-crest corals and indicated that shelf had a gentle and extensive ramp-style slope which dampened wave development (Multer et al., 2002).

However, these later investigators have failed to pose a more important question: if corals grew in shallow water, then what prevented them from reaching the +6 m highstand? Why was reef development largely restricted to elevations below +3 m and why did it not reach the +6 m highstand attained by the oolitic shorelines either side of the reef tract? Tentative evidence suggests that reef development may have been curtailed by shifting sediment associated with enhanced ooid production during the +6 m highstand. But this needs to be confirmed by precise radiometric ages of both reef and oolitic units.

## Bahamas

Similar reef development during the LIG has been reported from the adjacent Bahamian archipelago, but it has been characterized best on the island of San Salvador (Curran and White, 1989; Hattin and Warren, 1989; Chen et al., 1991; White et al., 1998; Wilson et al., 1998). There, detailed mapping shows that reefs also reached a maximum elevation of +3 m, and had a simple facies association consisting of a reef-crest, dominated by clasts and colonies of *A. palmata*, flanked by back-reef and a lagoonal zone composed of large patches of *A. cervicornis* and species of *Montastrea* (Figure 3). Above this reefal unit, the marine sequence is dominated by a shallow subtidal and beach-sand lithosome which reaches an elevation of +5 m consistent with a +6 m highstand (Carew and Mylroie, 1997). A similar sequence was reported from the southern end of the island by Hattin and Warren (1989), who documented patch reefs up to +3 m that were topped by a 30 cm cap of the

branching coralline algae. Subsequent development of a separate but poorly developed patch reef above the coralline cap up to 3.5 m was taken to be evidence "...of a slight additional rise of sea level. ..." (Hattin and Warren, 1989, p. 26). From this evidence, they concluded that there was a widespread phase of reef development associated with a +3 m stillstand of SL, followed by a rise to +6 m that was associated with a higher-energy beach and shallow subtidal sequence.

On both San Salvador and Great Inagua further south, systematic dating of the +3 m LIG reef unit revealed that this simple facies association had a rather complex age structure (Chen et al., 1991). Of the 11 samples with strictly reliable isotopic signatures, those taken from in-place corals in the patch reefs were stratigraphically consistent and clustered around 122 ka. But ages from the underlying coral-gravel unit gave a wider range of 122–130 ka, with five ages in excess of 127 ka (Figure 3). Closely juxtaposed samples from that unit also showed large variability of ~5,000 years between corals separated by only a few centimeters (e.g., samples M1, A, and D in Fig. 3a of Chen et al., 1991, p. 88). Although Chen et al. (1991, p. 83) warned that "storms can mix as rubble corals of different ages," well-dated 3 m sections of Holocene and late-glacial reefs show variability no larger than 1,000 years (Blanchon et al., 2002; Edinger et al., 2007). As a consequence, it is unlikely that large magnitude age variability in closely spaced corals from the Bahamian reefs resulted from mixing during hurricanes, as claimed by Chen et al. (1991), but resulted instead from mobilization of U and Th isotopes during diagenesis (Scholz and Mangini, 2007). Coral ages from this unit are therefore unreliable for determining the onset of the sea-level highstand, and cast doubt on the extended duration of the interglacial highstand claimed by Chen et al. (1991).

In addition to the duration of the LIG, these dates have also been used to identify the timing and significance of an internal reef-erosion surface discovered on Great Inagua (White et al., 1998; Wilson et al., 1998). A 1,500-year age difference between coral ages recovered from either side of this surface was taken to indicate that the highstand reef sequence was interrupted by a brief SL fall from +4 m to below the modern datum, and then a rapid rise back to +6 m (White et al., 1998; Wilson et al., 1998). Unfortunately, the 2 ka analytical age uncertainty and large true-age variation in corals dated by Chen et al. (1991) precludes their use in determining the timing of events of such short duration. Furthermore, although there is extensive evidence of marine truncation and bioerosion of corals and their clasts under this surface, there is no reliable evidence of emergence that can be separated from emergence that occurred at the end of the highstand. As a consequence, the evidence for a SL fall is based entirely on marine-erosion which is a common process not specific to that cause.

The +3 m reef unit has also been identified on several other Bahamian islands (Neumann and Hearty, 1996; Hearty and Neumann, 2001). On most of these, reef

**Last Interglacial and Reef Development, Figure 3** Stratigraphy and architecture of the LIG reef terrace from stable sites along the southern passive margin of the North-American Plate. Reef development to +3 m is widespread, but above this elevation reefs are absent in all areas except the Yucatan. Reef absence above +3 m in these areas is replaced by other evidence of a +6 m highstand, such as intertidal notches and sediments. In other words, all sequences support a highstand during the LIG of +6 m but, in most areas, reef development ceased by the time SL reached +3 m. Back-stepping in reef sequence from the Yucatan implies this absence was caused by a SL jump from +3 to +6 m. In most areas, the jump rapidly inundated broad coastal tracts, enhancing sediment flux and altering transport pathways, and this led to widespread reef demise. Reefs only survived in limited areas that were naturally protected from the new sedimentation regime.

development is vertically restricted to less than +3 m. As on San Salvador, however, intertidal beach units and notches clearly indicate that the highstand reached +6 m. Neumann and Hearty (1996) claimed that the general absence of reefal units above +3 m indicated that there

must have been a rapid jump in SL toward the end of the highstand with a duration that was too short for reefs to keep up or even to catch up. In fact, they claimed that there was only sufficient time for notch cutting, which was estimated at 600 years. To account for the well-preserved

nature of the reef surfaces, they argued that the fall from the brief highstand must have been as rapid as the preceding rise, and that the reefs therefore had little time for modification in the marine environment. The brief duration of the +6 m highstand was contested by Carew (1997), who suggested that a slower rate for notch erosion was more representative and gave a duration of 3,000 years as a better estimate. He also questioned the significance of reef preservation indicating that the well-preserved reefs were more likely to have been rapidly entombed by mobile subtidal sand bodies before SL regression.

### Grand Cayman

An almost identical sequence of reef development has been reported from Grand Cayman (Jones and Hunter, 1990; Hunter and Jones, 1996; Coyne et al., 2007), where a lower lagoonal patch-reef unit developed over a wide area but never exceeded an elevation of +3 m (Jones and Hunter [1990] reported patch reefs up to 3.8 m, but these were later corrected to 2.8 m in Jones [1994, p. 32] and Coyne et al. [2007, p. 550]). The patch reefs in this unit were protected to the northwest by a reef tract, also with a +3 m elevation. In most areas, the lower patch-reef unit is overlain by cross-bedded oolitic sands that develop up to an elevation of +6 m. The base of cross-bedded unit is marked by a discontinuous marine-erosion surface which is consistent with an abrupt switch to a high-energy subtidal to intertidal setting. Although Jones and Hunter (1990) interpreted this sequence to represent a simple shallowing-up succession, they omitted to explain why reef development was restricted to +3 m. They also suggested that the erosion surface represented scour during storms, but did not explain why storm waves and shifting sands were suddenly able to invade large areas of an extensive and apparently well-protected lagoon where patch reefs with delicate branching corals had previously flourished.

Later Coyne et al. (2007) suggested that cross-bedded units were younger based on  $^{230}\text{Th}$  ages of marine gastropods. Unfortunately, these ages failed any reasonable measure of isotopic reliability due to open-system diagenesis and were given priority over basic stratigraphic relations, which showed conformable transitions between the patch reef and cross-bedded units in several areas (including newly reported cores from George Town Harbor). As a result, the claim that these units are significantly younger is unsupported by reliable data.

Along the northeast coast of Grand Cayman, Vèzina et al. (1999) also reported a +3 m patch-reef sequence of LIG age adjacent to a relict sea-cliff with a notch at +6 m (Figure 3). Using closely spaced cores, they demonstrated that reef development overlapped the cliff base and reached an elevation of +2.6 m. In the outer part of the section, patch reefs aggraded vertically and then prograded horizontally seaward, as if constrained by a stillstand of sea level (Vèzina et al., 1999). The lack of reef development or any sediment above +3 m was interpreted as

being due to submergence in a lagoonal setting with a +6 m SL. However, in the absence of a preserved reef-crest unit (due to modern coastal erosion) this interpretation is equivocal and ignores the progradation of patch reefs and the fact that, in modern lagoons, patch reefs commonly reach mean low water.

From the foregoing, it is clear that reef sequences in Florida, the Bahamas and the Caymans flourished up to an elevation of +3 m but no higher. The fundamental question is why were reefs restricted to this elevation when there is abundant evidence that SL peaked at +6 m? The claim of Neumann and Hearty (1996) that sea level jumped to +6 m is a possible explanation, but falls short in accounting for why reefs did not recover. Even if the rise was transient, and lasted 600 years as claimed, reefs could have accreted 6 m in that time assuming a conservative accretion rate of 10 mm/years. Clearly something happened during the rise from +3 to +6 m that inhibited reef development in these areas.

### Northeast Yucatan Peninsula

A possible answer to this problem has recently been provided by Blanchon et al. (2009), who reported two superimposed fossil reef-crest units from the northeast Yucatan, one at +3 m and the other at +6 m (Figure 3). Reliable radiometric ages confirmed that both crests were of LIG age, between 125 and 117 ka, but could not differentiate between them due to subtle diagenetic alteration of corals in the lower unit. The relative-age of the two units, however, could be determined from their facies differences and contact relationships. The lower-reef tract at +3 m consisted of an *A. palmata* crest flanked by an *A. cervicornis*-dominated reef-front and a large lagoonal patch-reef complex that extended 200 m inland. Framework in the lower-tract had a cap of coralline algae and, in places, was leveled by a discontinuous marine-erosion surface. The upper-reef tract at +6 m initiated atop the seaward edge of the lagoonal patch-reef complex. But in this new location reef development was significantly different. In the lagoon, frameworks were dominated by a sediment-tolerant assemblage of branching coralline algae and *Porites*. They also lacked a cap of corallines, and were instead infiltrated by beach-derived shell-gravels from regressive shoreface deposits above. This infiltration pattern shows that the upper reef must be younger and was active shortly before SL fell from its highstand.

The cap of corallines on the older +3 m crest attests to its rapid demise and the discontinuous marine-erosion surface indicates that a patchy demise of corals also took place in the lagoon. Importantly, however, areas of continuous accretion between the lower patch-reef complex and the overlying tract require that lower-reef demise was ecologically synchronous with upper-reef initiation. Furthermore, in the upper tract, reef-flat development above +5 m and large in-place colonies of *A. palmata* at the base of the upper-crest unit indicated that SL must have jumped from +3 m to more than +5 m to drown the lower reef and

accommodate the back-stepping of the upper reef (Blanchon, in press). This jump also created a higher-energy wave field that mobilized back-reef and lagoonal sediments, creating a high sediment flux which smothered and eroded lagoonal framework, prevented the recovery of the submerged reef-crest, and suppressed coral framework in the lagoon (Blanchon et al., 2009).

A jump in SL, that caused reef drowning and back-steeping in the Yucatan reef sequence, can also account for the lack of reef development above +3 m in low-lying areas like the Bahamas and Grand Cayman. This is because the SL rise rate during the jump was sufficient to outpace the reef-accretion rate, and submerged +3 m reef tracts everywhere. This rapid depth change induced a higher-energy wave field that not only remobilized lagoonal sediments and buried or eroded adjacent reef framework, but led to a switch in sediment regime by suddenly providing extensive shallow-water areas for the generation of marine sand bodies. This increase in sediment flux prevented many of the submerged reefs from recovering after the rise, and led to a widespread suppression new reef development in low-lying areas. Along narrower, steeper shelves with smaller sediment reservoirs, a lower sediment flux after the jump enabled reefs to recover and back-step to new upslope positions.

### Western Australia

Reef-terrace development at +3 m not only occurs in stable areas of the Caribbean, but has been widely reported along the coast of Western Australia. In a review of Plio-Pleistocene deposits, Kendrick et al. (1991) reported intermittent development of a coral-reef terrace for 2,000 km along this coast, from Cape Range in the north to Cape Leeuwin in the south. Such extensive reef development provides an ideal opportunity to identify the controlling factors on reef development, such as the rate and magnitude of sea-level rise, and to compare those factors with other LIG reef provinces, such as the Caribbean.

The most northerly report of LIG reef development occurs at Cape Range, in the Canarvan Basin, where a fringing-reef forms a narrow coastal terrace running alongside the modern Ningaloo reef. In some areas, the terrace extends inland and consists of small patch reefs and lagoonal sands and gravels (Kendrick et al., 1991). Several sections in this area were investigated by Stirling et al. (1998), who reported the  $^{230}\text{Th}$  age of reef framework in the narrow coastal terrace at +3 m. Two of those locations yielded several strictly reliable ages: interior lagoonal patch reefs at +2 m in Mangrove Bay, gave ages from 116.1 to 119.2 ka, whereas a +3 m coastal reef tract further south at Yardie Creek gave four ages between 119.8 and 121.6 ka with two outliers of 124.6 and 126.8 ka (Figure 4). Drilling on the +2 m terrace at Tantabiddi Bay, just north of Mangrove Bay, recovered framework as deep as 10.3 m below SL, but no characterization of the core was provided (Stirling et al., 1998).

Further inland, along the sheltered coast of the Sandalwood Peninsula, Greenstein et al. (2005) discovered a marine-erosion surface truncating a +1.5 m reef terrace. Some areas of this surface were recolonized by sparse coral heads, but evidence of subaerial exposure was absent, making it identical to other marine-erosion surfaces reported from LIG reef deposits elsewhere.

At Cape Cuvier a little further south, O'Leary et al. (2008a) reported fringing-reef development in a coastal terrace that sloped inshore from +3 to +5 m. Like the terrace to the north, corals on the surface were truncated and capped with a layer of coralline algae. But unlike elsewhere, this coralline cap extended further upslope to +8 m, where it covered the inclined wave-cut surface of the underlying tertiary eolianite (Figure 4). Above that elevation was a coral-cobble beach gravel. Unfortunately, all  $^{230}\text{Th}$  ages measured from corals in this exposure had isotopic signatures associated with open-system diagenesis, but they clearly indicate a LIG age for the deposit. At Shark Bay, 200 km further south, O'Leary et al. (2008b) also documented reef development in a horizontal coastal terrace at +2.5 m. This terrace yielded isotopically reliable but stratigraphically inconsistent ages between 125.4 and 128.8 ka.

Continuing south into the Perth Basin, several sites have been investigated around Geraldton, including Burney and Leander Points on the mainland, and particularly the Houtmann Abrolhos Islands some 60 km offshore (Figure 4). In the Abrolhos, the reef terrace normally reaches +2 to 3 m and, as in other places, is thinly capped by crustose corallines. This reef framework is then overlain by up to 2 m of skeletal sands and gravels deposited in shallow subtidal or intertidal conditions. An exception to this sequence is found on east Wallabi Island at Turtle Bay, where the top of a domal exposure of reef framework reached +4 m and lacked the normal cap of coralline algae (Zhu et al., 1993). Subsequent drilling and dating of the Turtle Bay unit by Eisenhauer et al. (1996) gave two reliable surface ages of 124.0 ka and an outlier at 130.2 ka, and recovered 32 m of branching-coral framework. Drilling was also performed on the +2 m terrace at Rat and Roma Islands in the Easter Group of the Abrolhos by Collins et al. (1993). Both sequences were again dominated by branching corals but showed abundant encrustation by corallines. Only one reliable age of 124.0 ka was recorded from the surface exposure on Rat Island.

More successful dating of the +2 to 3 m reef terrace has been made on the adjacent mainland sections at Burney and Leander Points (Stirling et al., 1995, 1998). Interestingly, both these sections recorded multiple reliable ages that were similar to the Abrolhos. At Leander point, corals from a 1.5 m interval just above sea level recorded six ages from 121.8 to 124.2 ka with a single outlier of 126.6 ka. Similarly at Burney Point, four corals from a 1.3 m interval at the top of the terrace recorded ages between 121.7 and 123.5 ka. Clearly, these data convincingly demonstrate that coastal reef terrace in this region had a restricted interval of development between 124 and 122 ka.

**Last Interglacial and Reef Development, Figure 4** Cores and coastal sections from the LIG reef terrace from sites along the stable western Australian passive margin of the Indo-Australian Plate. Like other passive-margin sites, reef development to +3 m is widespread but, above this elevation, reefs are absent in all areas except Cape Cuvier (which is consequently thought to be a site of local uplift). Other evidence of a +6 m highstand, such as sub- and intertidal sediments, has been documented in most of these areas. This again suggests that all sequences support a highstand during the LIG of +6 m but, in most areas, reef development ceased by the time SL reached +3 m. As yet, back-stepping reef units have not been found in this region. When corrected for stratigraphic consistency, strictly reliable ages from several sections show that this +3 m reef development occurred within a restricted interval from 124 to 120 ka ago.

The reef terrace at Burney Point was also described in some detail by Johnson et al. (1995), who documented a wave-sculptured disconformity surface at +1 m overlain by a collapsed thicket of robust-branching *Acropora* that reached an elevation of +3 m (Figure 4). The disconformity preserved beneath the reef unit at this site has been used as an analog for the erosion surface described from Devils Point, Great Inagua, in the Bahamas (Wilson et al. 1998). Although the surfaces are similar, in that they are both bioeroded and encrusted, the surface at Burney Point has been highly sculptured by wave-erosion producing a widespread ridge-and-runnel system with a relief of 30 cm. Neither the erosion surface from the Bahamas, nor those in any other LIG reef sequence described so far, have this kind of wave sculpturing, which should be present if they had experienced a double passage of the intertidal shoreface during a meter-scale negative SL excursion.

The LIG reefs in the Abrolhos Islands and near Geraldton coincide with the present limit of modern-reef development. But unlike the modern reefs, LIG reef development continues south, and the +3 m reef terrace has been reported a further 350 km south at Rottneest Island, as well as in Foul Bay near Cape Leeuwin, some 550 km south of the modern-reef limit. Reef development at Rottneest Island is briefly described by Playford (1988) and dated by Stirling et al. (1995). At Salmon Bay, on the south coast of the Island, a coastal exposure of reef framework dominated by branching and tabular *Acropora* species reaches +3 m (Figure 4). Corals from this exposure returned five ages between 124.9 and 126.2 ka and an outlier of 127.3 ka. At Foul Bay, McCulloch and Mortimer (2008) reported a 1 m thick reef unit that reached +2.8 m which consisted of toppled and in-place head corals and coralline algae. Corals in this 1 m thick

unit returned isotopically reliable ages from 125.0 to 128.4 which is a significant age range considering the limited thickness of the unit. This lack of stratigraphic consistency indicates these ages may be suspect.

The expansion of sub-tropical reefs some 550 km past the modern limit of reef development, clearly indicates warmer sea temperatures than present during the LIG (Kendrick et al., 1991). This expansion was examined in detail by Greenstein and Pandolfi (2008), who contrasted modern and Pleistocene coral-assemblage pairs from Cape Range to Rottnest Island, a latitudinal gradient of 12°. They found that in the north, between Cape Range and Abrolhos, modern and fossil reefs had similar assemblages. But for sites further south, from Geraldton to Rottnest, coral taxa were different and fossil reefs were dominated by acroporas (*A. palifera*, *A. humilis*, and *A. hyacinthus*). In other words LIG reefs at Rottnest Island had a coral assemblage equivalent to the northern modern reefs, rather than the present assemblage around the island. This could be a preservational bias due to erosion of the fossil reefs, but of the 31 fossil taxa, 8 had significantly expanded ranges. In addition, corals such as *A. palifera*, which today is only found north of Cape Range, occurred south of the Abrolhos during the LIG. These results are clearly consistent with a shift in the biogeographic boundary of reef development and also a reduced latitudinal temperature gradient during the LIG.

In terms of timing of the biogeographic shift, Greenstein and Pandolfi (2008) assumed that the range expansions of coral taxa were contemporaneous and that reef-building events occurred during the same time interval. However, an analysis of the geochronology of reef development at the same sites by McCulloch and Mortimer (2008) concluded that the expansion of these taxa may have been confined to the early part of the LIG between 129 and 125 ka. Such claims are clearly hinged on the reliability of the  $^{230}\text{Th}$  ages and, given that there has been little assessment of the true-age variation in corals at these sites it is difficult to rule out the possibility that apparent age differences between the LIG reefs of Western Australia are merely dating artifacts due to subtle diagenetic processes, perhaps related to the increasing aridity to the north.

From the foregoing, it is abundantly clear that there was widespread reef development along the coast of Western Australia during the LIG. Of the 16 sites described above, 12 have a reef terrace at or below +3 m which is consistent with an initial +3 m SL position. Of the remaining four sites, three have reef terraces between +3 and +4 m. And the final site, at Cape Cuvier, shows evidence for two sea-level positions, with a reef terrace at +5 m and a coralline-encrusted shore platform up to +8 m. Although it has been claimed that the Cape Cuvier site represents evidence of a highstand greater than +6 m (O'Leary et al., 2008a), it is evident that the elevation of the reef and shore platform is anomalous in comparison with all other sites. This in itself is significant evidence for neotectonic activity, but is also supported

by the site's location on the western flank of the Cuvier Dome (Logan, 1987). Interestingly, if we assume that the reef terrace was uplifted from an original elevation of +3 m, then this implies that sea level must have subsequently risen to highstand of +6 m at the end of the LIG – a conclusion that is supported by elevations of SL indicators from other parts of Australia (Murray-Wallace, 2002).

Stratigraphic analysis of the radiometric ages of corals in the +3 m reef terrace indicates that widespread reef development along the Western Australian coast was confined to a much narrower time window than implied by the simple spread of ages alone (Table 1). Clearly, the amount of time represented by a 3 m interval of conformable reef framework depends directly on the rate of reef accretion and the precision of the age determination. During the last deglaciation, for example, reefs accreted at rates of up to 3 m in 375 years during the rapid postglacial SL rise (Blanchon, this volume). Measurement of the extrinsic age variation in uplifted Holocene reefs on the Huon Peninsula shows that a 3 m stratigraphic interval took no more than 1,000 years to develop (Edinger et al., 2007). Assuming the conservative estimate and an analytical error of 1,000 years, this indicates that the age of +3 m reef terrace along coastal areas of Western Australia should vary by no more than 1,000 years,  $\pm 1,000$  years (Blanchon et al., 2009). As shown in Table 1, Yardie Creek in the north, Burney and Leander Points in the centre, and Rottnest Island in the south all have strictly reliable age ranges of <2 ka and are therefore stratigraphically consistent. The mean ages from these sites indicates a restricted age of reef development between 120 and 124 ka for all but Rottnest Island where the average age is 126 ka.

## Hawaii

In addition to areas that have been largely stable since the LIG, there are some areas that have undergone minor amounts of gradual uplift thereby better exposing reef development. For example, adjacent to the island of Hawaii, where active volcanic loading has depressed the lithosphere, lies the smaller island of Oahu. This island sits upon the peripheral bulge of the loaded crust and, in contrast to the bigger island, has undergone slow uplift which has preserved and elevated LIG deposits up to +13 m (Muhs et al., 2002). These deposits consist of in-place reef framework, overlain by erosively-based intertidal skeletal sand and gravel units, but very few have been reported in any stratigraphic detail (Stearns, 1974; Ku et al., 1974; Sherman et al., 1993; Szabo et al., 1994). Recently Muhs et al. (2002) reported an extensive data set of 37 high-precision  $^{230}\text{Th}$  ages from this island and claimed that the duration of the LIG extended from 136 to 115 ka and therefore predated the insolation peak as claimed by Szabo et al. (1994) on the basis of less precise ages. However, there are significant problems with this analysis. First, Muhs et al. (2002) considered all ages with initial ratios of  $149 \pm 8$  per mil as reliable, rather than

**Last Interglacial and Reef Development, Table 1** Summary of age, elevation, and character of coastal reef terrace, Western Australia

Column 1: Cape Range (CR), Shark Bay (SB), Houtmann Abrolhos (HA), Cape Leeuwin (CL). References: 1, Stirling et al. (1995); 2, Stirling (1998); 3, Greenstein et al. (2005); 4, O'Leary et al. (2008a, b); 5, Eisenhauer et al. (1996); 6, Johnson et al. (1995); 7, Playford (1988); 8, McCulloch and Mortimer (2008). Column 3: Strictly reliable (SR) ages range defined by initial  $^{234/238}\text{U}$  of  $149 \pm 4$  per mil. Column 4: Stratigraphically consistent (SC) age range from strictly reliable, in-place corals within a conformable section within 3 m of each other, and with an age variation of ~2,000 years or less. Column 6: T, tabular; E, encrusting; B, branching; rB robust branching. Note: Age variation in Holocene reefs is <1,000 years for conformable 3 m intervals of framework (i.e., 3 m is the amount of reef accretion that can occur in 1,000 years; Edinger et al., 2007). For the LIG therefore, age variation should not exceed ~2,000 years (1,000 years  $\pm$  1,000 year analytical error).

adopting the more conservative ratio of  $149 \pm 4$  per mil which is considered by others to be “strictly-reliable” (Gallup et al., 1994; Stirling et al., 1998). Also, only two exposures of in-place coral framework were dated, and both returned a large spread of ages that are inconsistent with limited stratigraphic interval of reef accretion. The other ages reported by Muhs et al. (2002) are from coral storm-gravel deposits and their stratigraphic consistency cannot therefore be assessed. But of the 16 ages in the entire data set with strictly reliable initial ratios, 11 fall within the more restricted interval of 123–118 ka, suggesting a much narrower time window for highstand reef development than claimed by Muhs et al. (2002). These more reliable data are fully consistent with the orbital forcing of climate during the LIG (Muhs, 2002).

### Summary and conclusions

The age, elevation, and architecture of fossil reefs from both uplifted and stable terrains provide key insight into the timing, duration, and nature of the LIG. Uplifted areas provide an assessment of the timing of postglacial SL rise (or glacial termination) and the duration of the interglacial but, due to the tectonic overprint and the possibility of coseismic displacement, it is difficult to infer anything about the detailed SL behavior or the absolute elevation reached during the highstand. By contrast, stable sites can provide a detailed look into the timing and duration of peak interglacial conditions during the highstand, as

well as the absolute elevation and SL behavior during that highstand.

Without doubt, the best studied uplifted reefs of LIG age occur on Barbados and the Huon Peninsula of Papua New Guinea. Reef development on Barbados is well understood largely due to the fact that the relatively simple coral zonation on modern Caribbean reefs is well represented in its fossil counterparts (Jackson, 1992). The uplift of the LIG terrace on the south and west coasts of the island has exposed only the upper ~20 m of reef-crest development and, although earlier workers claimed that reefs were absent until later in the postglacial rise, this is difficult to substantiate now that reefs of late-glacial age have been encountered in submerged cores off the south coast (Fairbanks, 1989). It is much more likely that this 20 m thick reef-crest sequence represents the final back-stepping stage of reef development during the penultimate deglacial SL rise, and that earlier stages are buried beneath subsequent development of interstadial reef terraces (Blanchon and Eisenhauer, 2001). Aside from the incomplete record of reef development, the 20 m-thick reef-crest units display a clear keep-up architecture as demonstrated by their over-thickened facies which retrograde upslope on the west coast and aggrade vertically or prograde on the south coast. The timing and duration of this keep-up reef development, however, has been difficult to substantiate due to subtle diagenetic exchange of U-series nuclides in the fossil corals. This process has produced a 20 ka range of “strictly reliable” coral ages from

135.8 to 115.8 ka which shows little change even when corrected for such open-system effects (Gallup et al., 2002; Thompson and Goldstein, 2005). Yet a continuous 20 m-thick unit of reef-crest corals could develop in a mere 7,000 years using conservative rates of reef accretion, and in as little as 3,000 years at maximum rates. Given the lack of breaks in the reef-crest sequences on Barbados and the large true-age variation between closely spaced samples, it is highly unlikely that this timing or duration is accurate. Indeed, higher precision dating of speleothems has recently shown that Termination II started at 129 ka (Cheng et al., 2009) and implies therefore that the coral ages are inaccurate.

Although the timing and duration of reef development on the Huon Peninsula is similarly afflicted by open-system effects, the greater rates of tectonic uplift have exhumed almost the entire deglacial and interglacial reef sequence. Sections through the upper 30 m of the fossil fringing barrier-reef complex show that the barrier crest and slope facies are over-thickened implying a keep-up response to SL rise. Although supported by an exposure of shallow-water corals 90 m below the barrier crest, the interpretation of a keep-up architecture for the entire sequence is premature because catch-up responses may be obscured by the more complex reef zonation scheme found in the Pacific region. In addition, this complexity has made it difficult to reconstruct the internal architecture of the terrace and delineate separate stages of reef development. In turn, this has led to an unhealthy reliance on radiometric age inversions in establishing reef stratigraphy, and has resulted in ill-conceived claims of double highstands and extreme SL excursions.

There are also two main stable regions around the world where LIG reefs have now been well studied: the southern passive margin of the North-American Plate (Florida, Bahamas, Caymans, and the Yucatan), and the western Australian passive margin of the Indo-Australian Plate (from Cape Range to Cape Leeuwin). Remarkably, all sites in these two regions show almost identical reef development at identical elevations and therefore have likely had identical relative sea-level histories.

LIG sites in these regions show a ubiquitous and extensive stage of reef development that reached +3 m and consisted of reef-crest units with intertidal encrusters, and back-reef and lagoonal patch reefs that in several areas coalesced to form extensive flat-topped units (Yucatan and Florida). The character and elevation of these units is therefore consistent with reef development during a SL stand of +3 m. In Western Australia, these +3 m reefs have a significantly expanded latitudinal range and extend 550 km beyond the modern limit of reef development. This widespread development and expanded range clearly represents the acme of reef development during the LIG. Yet there is compelling evidence to indicate that this +3 m reef stage was abruptly terminated before the next stage commenced and SL rose to its +6 m highstand. This is based on the discovery in all areas (including two of the uplifted sites) of a discontinuous marine-erosion surface

and capping of crustose coralline algae. Most interpretations of this erosion surface, termed the Devils-Point Event, have related it to a transient SL fall of several meters which exposed the reef unit to subaerial conditions for up to 2,000 years. Yet the discontinuous nature of this surface and an absence of any convincing evidence of subaerial exposure or intertidal sculpturing are inconsistent with such an interpretation. An alternative scenario is that it represents a marine-erosion event resulting from a SL jump that drowned the +3 m reefs (Blanchon et al., 2009). This scenario is also supported by reef-surface cap of corallines which implies that reefs died off suddenly while still submerged in the marine environment.

In all areas where the +3 m reefs have been documented, overlying deposits of LIG age clearly indicate that SL subsequently rose from +3 m to its final highstand at +6 m. In most of the areas investigated, however, the overlying sequence is non-reefal and composed of either shallow subtidal sands and beach-derived sand and gravel, or there is no deposition and the +3 m reefal units onlap a bedrock coast with a distinct intertidal notch at +6 m. An important exception to this general sequence, recently reported from the Yucatan, is the discovery of reef back-stepping and reef-crest development up to the final highstand elevation of +6 m (Blanchon et al., 2009). This clearly supports the idea that the SL rise to +6 m was rapid and drowned the +3 m reefs and caused reef back-stepping. But it does not explain why reefs survived and back-stepped in the Yucatan and yet perished in most other areas. A possible explanation might be that the jump to +6 m inundated large coastal tracts in these low-lying terrains and helped establish new sediment-production areas and transport pathways which prevented reef recovery and further development. Such a scenario is supported by sediment-tolerant reef assemblages in the back-reef and lagoonal zones of the +6 m reef in the Yucatan and indicates that even here reef development was not completely normal.

Although confirmation of rapid SL change during the highstand requires duplication of the Yucatan results, there are sufficient data to draw some final conclusions about the timing and duration of the highstand and how it compares with the full interglacial interval. As shown in Table 2, the duration of the LIG as measured from the range of strictly reliable ages in uplifted areas is 136–115 ka. However, very few of these ages are stratigraphically consistent and it is therefore not possible to determine a reliable estimate from these data. The duration of the highstand, as measured in stable areas from the range of strictly reliable ages, is slightly less, between 128 and 116 ka. However, even this reduced range is excessive when the amount of reef accretion is considered. For example, data from the Huon Peninsula indicate that the total amount of accretion during the LIG must have exceeded 90 m, yet reef accretion during the highstand was a mere 6 m. It seems very unlikely that this 6 m of accretion took 12 ka to develop. However, if the stratigraphic context of these samples is considered, and inconsistent

Column 1: References: 1, Gallup et al. (2002), Thompson and Goldstein (2005); 2, Stein et al. (1993), Esat et al. (1999); 3, Stirling et al. (1995, 1998); 4, McCulloch and Mortimer (2008); 5, Szabo et al. (1994), Muhs et al. (2002); 6, Chen et al. (1991); 7, Blanchon et al. (2009). Column 2: Strictly reliable (SR) ages range defined by initial  $^{234}\text{U}/^{238}\text{U}$  of  $149 \pm 4$  per mil. Column 3: Stratigraphically consistent (SC) age range from strictly reliable, in-place corals within a conformable section within 3 m of each other, and with an age variation of  $\sim 2,000$  years. Note that although Hawaii has the highest number of strictly reliable ages from the highstand, many of these are from coral gravels and their stratigraphic consistency cannot be determined. These ages could be used to determine the LIG duration assuming upslope transport from older reef deposits but it should be noted that ages measured by Szabo et al. (1994) are lower precision.

ages are excluded, the range is reduced to 8 ka from 128 to 120 ka. And in two of the stable areas with the most ages (NW Australia, Bahamas), this range is further reduced to 4 ka from 124 to 120 ka. The only area where a significant number of ages exceed this restricted range is in south Western Australia. Clearly, the possibility exists that even strictly reliable ages that are stratigraphically consistent can be altered by uniform diagenetic exchange of U-series nuclides.

In conclusion, more work is needed on defining the timing of the LIG by dating and documenting basal reef development in uplifted areas. This must include defining the architecture of shallow-water facies to determine if reefs kept pace with SL rise or back-stepped in response to jumps in that rise. For the highstand, more work is needed to document reef architecture in areas where only the 3 m terrace has been identified so that the progression of SL to +6 m can be determined. Finally, order of magnitude improvements in the analytical precision of U-series dating (Cheng et al., 2009) will allow a better assessment of stratigraphic consistency of ages from individual outcrops and should lead to the reconstruction of high-resolution SL curve and resolve conflicts between the timing and duration of the highstand and that of the LIG.

## Definition

Low Wooded Islands: A distinct type of reef island that occupies a reef platform surface and comprises three distinct biogeomorphic units: a windward shingle island or gravel ridges, a leeward sand island, and a central reef flat zone comprising mangrove.

## Introduction

The term “low wooded island” was introduced by Steers (1929, 1937, 1938) and Spender, (1930) to describe islands with a unique complexity of morphological and biological characteristics. The name is somewhat ambiguous with Spender (1930) preferring “island reef” and Fairbridge and Teichert (1947) suggesting “low wooded island reef”. Despite these differences in terminology, the descriptor “low wooded island” has become firmly established within scientific literature.

A synthesis of the largely descriptive accounts of low wooded islands allows their global distribution to be identified. The geographic location of these islands includes: the northern Great Barrier Reef (Steers, 1929), although Neil (2000) describes an analogous feature in Moreton Bay several hundred kilometers south of the Great Barrier Reef, the Indonesian reef archipelago including Jakarta Bay and the Java Sea (Umbgrove, 1928; Tomascik et al., 1997), Pigeon and Salt cays, Jamaica (Steers and Lofthouse, 1940), and the Belize barrier reef (Stoddart, 1965). Islands

consisting of gravel seaward ridges, leeward sand ridges, and central mangrove filled lagoons are also found on the peripheral rim of some mid-ocean atolls. However, because these latter islands are a component of a larger reef structure, with lagoons and numerous other types of islands, they are not considered low wooded islands.

Detailed descriptions of low wooded islands show that there are differences in morphological expression of biogeomorphic units between reef settings. Stoddart (1965) termed the Belize examples “moat islands” due to their morphological simplicity compared to those from the Great Barrier Reef, which are considered to have the greatest topographic complexity (Stoddart, 1965; Stoddart et al., 1978a). Much of the detailed understanding of the morphological components, sedimentology and evolution of low wooded islands is due to investigations in the northern Great Barrier Reef. This work was the result of two Royal Society Expeditions in 1929 and 1973, which produced comprehensive maps and descriptions of many islands. As a result of this intense scientific effort low wooded islands have become synonymous with the subset of 34 reef platform islands in the northern Great Barrier Reef. The data from these early investigations of low wooded islands have been collated and synthesised by Hopley (1982) and Hopley et al. (2007).

### Geomorphic characteristics

Low wooded islands are associated with relatively small reef platforms that range in area from 1 to more than 500 ha. Reef platforms generally have the following properties: high elevation, are located in regions with small tidal range, are sheltered from high-energy oceanic swell, and are in close proximity to mainland coasts.

While the basic distinguishing features of low wooded islands are the three biogeomorphic units, there is considerable variety in the size and morphology of each unit. Indeed, Stoddart et al. (1978a) argue that low wooded islands exhibit the greatest complexity of all reef islands. Typical examples and characteristic features of these islands, based on investigation of the Great Barrier Reef examples, are shown in Figures 1 and 2. These characteristics are described below following a cross-reef sequence from windward to leeward reef platform.

### Emergent reef flat

The reef flat, which is approximately 100 m in width, is emergent at low water levels and is laterally continuous enclosing the reef top (Figure 2a and b). On some islands the central reef top may also be emergent while on others it is an enclosed depression (Stoddart et al., 1978a). Due to the moderate energy environment of low wooded islands algal ridges are absent. Living coral is absent from the emergent reef flat, which is dominated by algae. However, many of these emergent reef flats have moated pools with living microatolls.

### Shingle ramparts

Asymmetric ridges of coral shingle occur parallel to the reef perimeter (Figures 1 and 2a). These ridges have gentle seaward slopes and steep landward slopes indicative of episodic storm-driven landward movement. In planform the inner edge of ramparts are arcuate with occasional shingle tongues extending on the order of 100 m across the reef. Eroding ramparts form basett edges (Figure 2b). Most islands have multiple ramparts, which when coalesced form shingle islands.

### Moats

Shingle ramparts can impound shallow pools on the inner reef flat. Drainage is impeded in the moats with ponded water supporting coral growth above the elevation of corals on the outer reef.

### Platforms or promenades

Conglomerate platform is commonly found on the outer seaward margins of mangrove and shingle ramparts (Figure 2c). Their genesis is related to migration and cementation of ramparts. On the Great Barrier Reef islands two distinct platform levels have been identified and linked to differing sea level stages (Figure 1g). On a number of low wooded islands dead microatolls also outcrop beneath the cemented platforms.

### Shingle islands

Shingle islands are commonly deposited upon the cemented conglomerate platforms. These islands consist of a series of shingle ridges, which may have coalesced, and which are colonised with vegetation (Figures 1 and 2d). The islands vary greatly in width and elevation. Dominant vegetation on these windward shingle islands includes: low mangrove (*Avicennia marina*, *Aegialitis annulata*); succulents (*Sesuvium*, *Salicornia*, *Suaeda*), and salt tolerant *Phemphis* bushes (Hopley, 1982; Stoddart et al., 1978a).

### Mangrove swamp

Mangrove communities of varying size occupy the central reef top. Stoddart (1980) recorded 15 species of mangrove from the low wooded islands of the northern Great Barrier Reef. Dominant species include *Rhizophora stylosa* and at higher elevations this is replaced by *Ceriops tagal*, *Bruguiera* sp., *Xylocarpus* sp. and *Osbornia* sp. *Rhizophora* and *Avicennia* are also identified as dominant mangrove species in descriptions of analogous islands on the Belize barrier reef (Stoddart, 1965) and Jamaica (Steers and Lofthouse, 1940).

Mangrove stands vary in extent from 1 to more than 125 ha (in the case of Bewick Island, GBR, Stoddart et al., 1978a). However, there is no relation between reef platform area and proportion of mangrove occupying the reef surface. These communities are considered opportunistic in that their presence and distribution depends on the position and dynamics of shingle ramparts and islands, and the

location and elevation of conglomerate and reef topography. In particular, shingle islands and ramparts afford shelter from wave and current energy providing a suitable low energy depositional environment for mangrove colonisation (Stoddart, 1965; Stoddart et al. 1978a).

The substrate underlying mangrove communities varies considerably and includes: sequences of organic mud that reach up to 2 m thick, sandy reef flat sediments, and emergent fields of fossil microatolls (Figure 1g).

#### Leeward sand cay

Supra-tidal sand accumulations occur on the leeward sides of low wooded islands and exhibit greater morphological diversity than ordinary sand cays (Stoddart et al., 1978a). These islands can be grouped according to their location with respect to other reef top geomorphic units, stability and degree of vegetation. In one group, sand cays can occur as discrete and separate features and possess similar characteristics to other reef flat sand cays (e.g., Figure 1a and b). These cays may occur as small, unvegetated and ephemeral features. Others are larger, stable vegetated islands (Stoddart et al., 1978a). These larger islands are commonly covered with woodland or scrub but

have a higher diversity of vascular plants than simple sand cays. A second group consists of discrete vegetated cays, which are surrounded entirely or partially by mangrove (e.g., Figure 1d–f). These islands form contiguous land units with the mangrove and shingle islands and collectively occupy large areas of the reef platform.

A notable feature of the vegetated sand cays of the Great Barrier Reef is the presence of an extensive high terrace surrounded by a lower elevation terrace (Figure 1g). The higher terrace is also distinct from the lower elevation counterpart due to greater soil development, different sedimentary characteristics (McLean and Stoddart, 1978), and more mature and dense vegetation communities. The different terrace levels are indicative of distinct phases of island development.

Stoddart et al. (1978a) note that sand cays have higher numbers of vascular plants than other vegetated cays in the Great Barrier Reef. Typically the higher terrace contains woodland comprising a mix of trees such as *Casuarina equisetifolia*, *Pisonia grandis*, *Pandanus*, *Cordia*, and Coconuts. Common at the fringes of woodland and on lower terraces are shrub species that include *Tournefortia*, *Pemphis*, *Scaevola*, and *Euphorbia* sp. that give islands a bushy appearance (Hopley, 1982).

On some islands lower terraces are characterized by open areas with creepers, herbs, and grasses. Particularly common in the Great Barrier Reef examples are the colonizers *Thuarea lepturus* and *Sporobolus*, the succulents *Sesuvium* and *Portulaca*, and creepers *Ipomoea* and *Canavalia*. A similar range of vegetation has been described from sand cays in the Belize barrier reef and Jamaica (Steers and Lofthouse, 1940; Stoddart, 1965).

### Boulder zone

A boulder zone is a recurrent feature of the leeward reef edge or sand cay shoreline. Reaching up to 4 m in diameter the boulders comprise individual coral colonies of storm deposited origin.

### Formation of low wooded islands

The boundary controls on the formation of low wooded islands are the same as other reef islands. Three factors typically constrain the development of islands. First, a physical foundation is required at or near sea level, which need not be extensive (Hopley, 1997) nor sea level constrained (Kench et al., 2005). Typically this foundation is a reef flat (Stoddart et al., 1978a) although some islands are situated upon lagoonal sediments (Kench et al., 2005). As noted by Stoddart (1965) the reef structure of low wooded islands differs between the Great Barrier Reef and Jakarta Bay. Nevertheless, these structural differences have no influence on island morphology. Second, a supply of sediment derived from the surrounding reef platform is required. Third, a process regime able to entrain, distribute and deposit sediments at different locations on reef surfaces is necessary (Stoddart and Steers, 1977).

The process controls on formation of each biogeomorphic unit are relatively well constrained. Shingle ramparts are considered to be storm wave deposited features with their presence and number on windward reef margins related to storm frequency and the recovery interval of reefs to generate sediment (Stoddart, 1965; McLean and Stoddart, 1978). The storm deposition of gravel deposits has a number of well documented analogues (Scoffin, 1993) such as the formation of sequential island ridges in Lady Elliot Island in the southern Great Barrier Reef (Chivas et al., 1986) and cyclone bank deposition in Tuvalu (Maragos et al., 1973). Sand islands are developed at leeward depocentres on the reef platform at the zone of convergence of swell, which refracts around the reef platform structure and waves that cross the reef flat at high tide. Their development is therefore, controlled by reef platform configuration and orientation with respect to the approach of swell energy and the supply and calibre of sediment on reef flats (McLean and Stoddart, 1978). Of note, the deposition of shingle ramparts disrupts the wave refraction signals propagating across reef surfaces. Consequently, modification of wave processes may have influenced the leeward depocentre and planform configuration of sand cays. It is generally accepted that mangrove colonisation of the central reef flat has occurred under low

energy conditions provided by shingle ramparts, which are conducive to deposition of finer sediments and establishment of mangrove.

Stoddart (1965) proposed a simple process model to account for the presence and distribution of low wooded islands and account for the different formative mechanisms and distribution of depositional products on reef platforms. This model is based on the relative interplay of exposure to wave energy, reef geometry, and sediment calibre. The characteristics of exposure include: variability and wind strength, effective fetch, water depth, and local factors of reef depth, which control incident wave energy. Low wooded islands occur in settings protected from high energy swell. They tend to occur where significant fetch length allows development of moderate wave energy. The moderate energy setting is considered conducive to more fragile branching coral growth forms, therefore, supplying the shingle sediment for ramparts (Steers and Lofthouse, 1940; Stoddart et al., 1978a). Stoddart (1965) concluded that wave action is a sufficient mechanism for both shingle ridge and sand cay formation.

Recognition that the process regime is able to account for the morphological development of low wooded islands has significant implications for the interpretation of regional differences in island morphology. In particular, sea level change can be discounted as a necessary precursor for island formation. However, regional differences in the patterning of Holocene sea level change and reef growth are likely responsible for observed differences in complexity of island morphology.

For example, in the Caribbean, sea level rose continually through the Holocene and slowed significantly over the past 1,000 years (Toscano and Macintyre, 2003). Low wooded islands described from this region have subsequently formed in response to the contemporary process regime at constant sea level position and produced a simple suite of morphological units. In contrast, Holocene sea level in the Indo-Pacific has been at or close to present level for the past 6,000 years with a 1 m highstand approximately 6,000–3,000 years ago (Chappell, 1983). This differing pattern of sea level has imparted a more complicated morphological imprint on low wooded islands.

Results from radiometric dating of reefs and islands in the Great Barrier Reef provides the most detailed dataset with which to place an age framework on the evolution of low wooded islands (Polach et al., 1978; McLean et al., 1978; Stoddart et al., 1978b).

The platforms which support these islands were developed at modern sea level 6,000–5,000 year B.P. Evidence from emergent reef platform and fossil microatolls indicate reef platforms accreted to elevations above present sea level in response to the mid-Holocene highstand. Radiometric ages on high sand cay terraces, beachrock, upper promenades and shingle ridges (Figure 1g) indicate an initial phase of island formation in the period 5,000–3,000 year B.P. with morphological products on the order of 1.0 m above contemporary counterparts.

A second phase of island development has occurred over the past 1,500 years at contemporary sea level producing lower sand cay terraces and shingle ridges. Consequently, the geomorphic complexity of low wooded islands in the GBR results from the long period during which reefs have been close to present sea level combined with distinct changes in sea level position, altering the base level upon which contemporary processes have been able to control island formation.

### Temporal development and morphological change

A number of early studies speculated about the developmental sequence of low wooded islands. Spender (1930) considered the islands to represent equilibrium forms, whereas Steers (1937), on the basis of the width and extent of ramparts suggested, they represented an evolutionary sequence. These ideas were expanded by Fairbridge and Teichert (1947) into an evolutionary sequence in which the increase in extent of mangrove was proposed as an indicator of relative maturity. A similar concept of age development was proposed by Umbgrove (1947) for the islands of Jakarta Bay. Shingle ramparts were observed in different positions across reef platforms and in some cases fused to the sand cay shoreline. Umbgrove (1947) proposed a developmental sequence in which shingle ridges migrate across platforms and fuse with sand islands. Island maturity was therefore linked to the association of shingle ridges with the sand cay.

These early theories of island development were largely based on field descriptions and time-space substitution. However, these models have been largely dispelled based on more detailed consideration of the process regime affecting reefs, the development of chronologies of island formation, and monitoring studies. For example, monitoring of islands in Jakarta Bay by Zaneveld and Verstappen (1952) failed to identify the morphological stages proposed by Umbgrove (1947).

Collectively, these latter studies have also provided a number of insights on the sequence of island development and geomorphic behavior. First, consideration of the process controls on island formation (Stoddart, 1965) and radiocarbon evidence (Polach et al., 1978; McLean et al., 1978; Stoddart et al., 1978b) indicates that shingle ramparts and sand cays may form independently or contemporaneously, but that mangrove colonization logically follows formation of shingle ramparts that afford protection from higher energy wave conditions.

Second, decadal scale monitoring and analysis has identified considerable geomorphic change in low wooded islands which includes: sand cay migration, rampart building, destruction and migration, and mangrove expansion and contraction (Verstappen, 1954; Stoddart et al., 1978c; Rasmussen, 1986; Frank and Jell, 2006). Of note, such changes display no regular or consistent pattern between islands. The principle causative mechanisms of these geomorphic changes are decadal scale variations

in climate (Verstappen, 1954), which reconfigure wave processes on reefs, cyclones, and storms (Moorehouse, 1933, 1936; Stoddart et al., 1978c).

Third, feedbacks are likely to exist that also modify island morphology. Examples include: shingle rampart dynamics modulating mangrove contraction or expansion, the configuration and extent of ramparts controlling wave refraction patterns on reef surfaces and sand cay shoreline processes, and mangrove expansion, which may shut down the process regime influencing shoreline change on sand cays.

Collectively, these observations suggest that each island has its own developmental sequence and ultimate morphological end point, which is determined by its unique combination of location, exposure, reef geometry and size, and sediment calibre, which is then modulated by changes in the boundary process regime.

### Summary

Low wooded islands are a specific and unique type of reef island that occupy the surface of reef platforms. They occur in a number of moderate energy reef settings where the combination of wave energy exposure, reef geometry, and sediment calibre are suitable for island formation. Scientific understanding of low wooded islands is heavily influenced by detailed investigations in the early to mid-twentieth century on islands in the Great Barrier Reef, Australia, recognized as the most geomorphically complex examples. However, since 1973 there have been few detailed studies of evolution or process controls on development of low wooded islands in the Great Barrier Reef or other reef settings. Consequently, global variations in the process regime controlling island development and the precise chronology of island formation are poorly resolved. There remain significant research opportunities to redress these gaps in understanding and develop a global model of the formation and distribution of these distinct island types.

## LYELL, CHARLES (1797–1875)

James Bowen  
 Southern Cross University, Lismore, NSW, Australia

Born in Edinburgh, Lyell became the dominant geologist of the early nineteenth century with his great three-volume *Principles of Geology*, published during the years 1830–1833. To explain the puzzle of atoll formation, he argued that the circular or oval forms of the numerous coral isles of the Pacific, with lagoons in their center, “naturally suggest the idea that they are nothing more than the crests of submarine volcanos, having the rims and bottoms of their craters overgrown by corals” built by an infinitely slow process on the summits of submerged volcanoes on the ocean floor by “branched madrepores.” In the case of archipelagos and similar distributions, Lyell believed they had been formed from the ejection of volcanic ashes and sand which served as the foundations for yet further reefs.

He also sought to explain the other great question puzzling explorers: why “there should be so immense an area in eastern Oceania, studded with minute islands, without one single spot where there is a wider extent of land than belongs to such islands as Tahiti, Hawaii, and a few others, which either have been, or are still the seats of active volcanoes?” The answer he provided was that

“the amount of subsidence by earthquakes exceeds in that quarter of the globe at present the elevation due to the same cause.” The uniformitarian argument of causes in continuous operation – today known as actualism – was advanced as demonstrative proof: active volcanoes certainly are brief catastrophic events, indicative of the release of subterranean energy, but they remain, none the less, mere transitory epiphenomena on the continuing

elevation and subsidence of the earth’s crust. The Pacific, he reasoned, has simply sunk as the underlying forces have been released, and in corresponding motion the nearby Andes had slowly risen out of the sea, carrying their marine depositions with them.

## MACNEIL, F. STEARNS (1909–1983)

---

David Hopley  
James Cook University, Townsville, QLD, Australia

Darwin's 1842 model for atoll development provoked numerous alternative ideas including antecedent platforms, eustatic sea level oscillations, and integrated hypotheses. Japanese researchers were the first to consider that modern reefs are growing on limestone platforms exposed to sub-aerial weathering during lower sea level periods of the Pleistocene (Asano, 1942; Yabe, 1942; Tayama, 1952). Their papers, however, were largely ignored or dismissed (e.g., Umbgrove, 1947) until the ideas were redeveloped in the American literature. Initially Stearns (1946) believed that variations in sea level were major factors in producing the relief of atolls and in particular, internal unconformities where the reef limestone was eroded or exposed during low sea levels.

However, the paper published in 1954 by F. Stearns MacNeil of the US Geological Survey has become the most widely quoted source of the hypothesis of an inheritance from sub-aerial forms for the shape of atolls. Interestingly, MacNeil notes that Hoffmeister and Ladd (1944) had previously concluded that the saucer shape of many uplifted Pacific limestone islands was due to solution, and not to the fact that they were raised atolls, yet they did not develop the argument in their exposition on antecedent platforms. MacNeil's theory recognized the importance of organic growth during periods of submergence but placed at least equal importance on the role of solution in fashioning the lagoonal depressions and annular rims of atolls. Case-hardening and development of underground drainage systems were seen as important factors in the development of the sub-aerially exposed limestone

surface. MacNeil, in the introduction to his 1954 paper, stated:

Though it is true that most authors have sought to explain barriers and atolls as the ultimate forms of reefs, the inclusion of all reef hypotheses under one heading implies more conflict than really exists. Generally no distinction is made between theories dealing mainly with the foundation of reefs, and the shape of reefs. There is a general feeling among investigators at present that atolls are not always formed the same way, and therefore no one theory can explain atolls.

and later:

It would seem that each atoll should be studied as an individual and it is not thought that the present hypothesis, believed to be true for the oceanic atolls of the mid Pacific, is necessarily true for the atolls (*sic*) of the Great Barrier Reef.

*MacNeil, 1954. pp. 402–403*

It is possible here that MacNeil was too conservative in his application of his hypothesis, for Purdy (1974) has greatly extended the antecedent karst model to explain the configuration of all reefs by means of preferential reef accretion on topographic highs in underlying subaerially weathered surfaces. However, MacNeil's statements implying that the coral reef problem has been largely a matter of confusing structure and surface morphology, and of assuming that all reefs have a similar evolution, are an illumination of the problem not previously considered. It is from about the time of his paper that general models of reef evolution have become unfashionable, a trend that is noticeable within geomorphology generally, as indicated by Higgins (1975). Higgins attributes this decline in landscape models to a change in the intellectual climate resulting from increasing quantification and interest in process, which in turn have suggested that complex landforms may be explained by more than one hypothesis.

## MAKATEA

---

Lucien F. Montaggioni  
 University of Provence, Marseille, Cedex 3, France

## Definition

*Makatea* is defined originally as an elevated (uplifted) rim of coral reef limestone wholly or partly surrounding a volcanic island. Makatea islands refer to composite islands according to Nunn (1994) as they possess three distinct geomorphic features from the shoreline inwards: a makatea limestone, a depression with swamps and streams, and an exposed volcanic core.

*Etymology*: The term *makatea* was originally defined and used in the southern tropical Pacific (Cook Islands). It derives from the Polynesian language, probably from two words: *maka* (slingstone) and *tea* (white).

*Origin*: The makatea limestone consists usually of Cenozoic reef material, locally with peripheral fringes of Quaternary reef terraces deposited before island uplift (see Montaggioni and Camoin, 1997; Vacher and Quinn, 1997 for reviews). The morphology of makatea islands frequently resembles that of modern barrier reefs or

almost-atolls in which topography is believed to be inherited from pre-existing karstic relief. In most cases, the depression behind the reef rim is the result of subaerial solution by freshwater (Purdy and Winterer, 2006). The final landscape is typified by upland depression-and-rim reliefs and coastal cliffs. The volcanic core has been built by different mechanisms in relation to lithospheric plate tectonics, e.g., hotspot, arc volcanism, and volcanism at or close to divergent plate boundaries. Similarly, uplifting has been controlled by a variety of regional tectonic processes.

*Parent feature*: The island of Makatea in the northwestern Tuamotus (French Polynesia) is a high carbonate, atoll-shaped structure, generally not regarded as a typical makatea island because of the lack of exposed volcanics in its central part. However, its present-day morphology has been produced by uplift of a Cenozoic reef tract, followed by subaerial, karstic erosion. The name of makatea island therefore is suggested to be used in a wider sense and thereby applied to any tropical Pacific island typified by uplifted reefal limestone severely karst-eroded.

## MALDIVES

---

Paul Kench  
 The University of Auckland, Auckland, New Zealand

## Definition

*Maldives*: The Republic of Maldives is an archipelago of coral atolls and reef platforms located in the central Indian Ocean.

## Introduction

The Maldives archipelago comprises a chain of coral reefs and reef islands situated 700 km southwest of Sri Lanka and positioned between the Lakshadweep Islands (to the north) and Chagos Islands (to the south). The archipelago

extends 868 km from Ihavandhippolhu in the north (6°57'N) to Addu atoll (0°34'S) just south of the equator. Comprising 2,041 reefs the archipelago is globally unique in biological diversity, the diversity of reef structures it possesses, and their mode of evolution. The reef system is host to approximately 1,190 low-lying reef islands. As one of only four atoll nations, the Maldives is commonly regarded as extremely vulnerable to future sea-level and climatic change.

### Early exploration

Earliest scientific investigations of the Maldives involved detailed hydrographic observations of the archipelago by Commander James Moresby 1835–1838. This work produced detailed hydrographic charts of the reef system, which were used by Charles Darwin in constructing his global synthesis of reef evolution, and which remain the most accurate records of bathymetry in the archipelago. At the end of the nineteenth century and beginning of the twentieth century a number of scientific expeditions were undertaken to the Maldives to document the taxonomy and biogeography of reef biota and make observations of oceanographic conditions. Most notable were the expeditions of James Stanley Gardiner in 1899–1900 who undertook the first detailed descriptions of marine and terrestrial fauna and flora as well as reef structures (Gardiner, 1903). Shortly thereafter, Alexander Agassiz also visited the archipelago in 1901–1902 and undertook sampling and description of biological aspects of the reefs (Agassiz, 1903). Seymour Sewell led the “John Murray” expedition to the Maldives (1933–1934) in which Sewell undertook detailed geomorphic observations of a number of atoll islands (Sewell, 1936a, b).

In 1957–1958 the “Xarifa” expedition undertook detailed investigations of the sub-littoral ecology and structure of reefs in many atolls in the archipelago (Hass, 1965). Introducing new systematic survey techniques, this expedition was notable for its taxonomic investigation of faunal and floral communities, identification of high species diversity, and establishment of baseline monitoring locations for future reference of reef community dynamics (Wallace and Zahir, 2007). British scientists also studied the marine and terrestrial geomorphology and ecology of Addu atoll (Stoddart, 1966).

Since these early expeditions the research effort in the Maldives can be described as sparse and narrowly focused on specific aspects of reef ecology, geology, and management. As a result large gaps exist in scientific knowledge and many atolls have not been visited by scientists since Gardiner and Sewell.

### Geologic history

The Maldives constitute the central section of the Laccadives – Maldives – Chagos submarine ridge, which in turn is part of a larger feature that stretches from the early Tertiary Deccan Traps of India to the volcanically active zone of Reunion. The Deccan Traps were the first

manifestation of the stationary mantle hotspot that subsequently produced the volcanic ridge underlying the Maldives. Northward drift of the Indian Plate and northeastward motion of the African plate has resulted in northward age progression along this ridge (Duncan and Pyle, 1988; Duncan and Hargreaves, 1990; Tiwari et al., 2007).

The history of formation of the Maldivian atoll systems differs from the subsidence model proposed by Darwin (1842). Rather, carbonate accumulation through the Tertiary was controlled by phases of aggradation and progradation modulated by large oscillations in sea level (Aubert and Droxler, 1992; Purdy and Bertram, 1993; Belopolsky and Droxler, 2003). The basement rocks underlying the Maldives are Eocene volcanics (55 million years old). These basement volcanics are capped by up to 3,000 m of limestones. Carbonate banks were initiated in the Eocene on topographic highs of the faulted volcanic basin (Figure 1). A number of NNE–SSW oriented grabens acted as channels that became filled with sediments shed from surrounding carbonate banks. The Oligocene to early Miocene were characterized by aggradation of carbonate banks and backstepping in response to sea level rise. An elevated outer rim developed and provided the antecedent structure for the double chain of atolls separated by an inner sea basin that characterizes the central section of the contemporary archipelago (Figure 2). The mid-Miocene (15–10 million years ago) was dominated by lateral progradation from the outer margins of the twin atoll chain toward the inner sea forming a shallow carbonate platform. This period of lateral progradation was followed in the late Miocene and Pliocene by flooding of the platforms and backstepping of the carbonate banks to the periphery of the platform. These peripheral platforms were exposed to karstification during the Plio–Pleistocene sea level minima.

During the Quaternary, the dominant mode of reef development has been vertical coral reef growth on top of these karstified remnants. This vertical reef growth is a consequence of high-amplitude sea-level fluctuations during the Pliocene–Pleistocene, producing alternate periods of exposure and submergence. The Holocene is the last of these reef growth phases.

The contemporary surface morphology of the Maldivian reefs is the result of coral reef growth over the past 10,000 years upon Pleistocene foundations. The Holocene reef growth history of the Maldives has only recently been resolved in detail based on drill cores from Ari and South Maalhosmadulu atolls with the Holocene reef thickness ranging from 12 to 14 m (Gischler et al., 2008; Kench et al., 2009). These studies show the Holocene reef growth initiated approximately 8,100 years ago as sea level flooded the Pleistocene surface. Vertical reef growth occurred at around 7 mm/year for the period 8,100–6,500 years ago and subsequently slowed to 1 mm/year thereafter. Evidence suggests the final stages of reef accretion in the late Holocene exhibited local variations. In situ reef deposits located above sea level on some reefs show

**Maldives, Figure 1** Schematic of the geological structure and evolution of the Maldives archipelago along a west to east transect through the central archipelago. Representative location of transect shown in Figure 2 (after Belopolsky and Droxler, 2003).

vertical reef accretion to a mid-Holocene highstand of approximately 0.5 m above present 2,500 years ago (Kench et al., 2009), where elsewhere the lack of higher sea level evidence suggests reef accretion may have lagged other sites (Gischler et al., 2008).

### Reef structure

The Maldivian archipelago consists of 2,041 individual reefs with a total reef area of 4,513 km<sup>2</sup> (Naseer and Hatcher, 2004). This complex network of reefs is organized into a number of distinct atoll and reef types. There are 21 atolls and 4 oceanic reef platforms.

Atolls can be divided into two types based on their broad physiographic characteristics. *Open atolls* are the dominant atoll type (16 in total) and are characterized by heavily dissected atoll rims, which in planform appear as a sequence of individual reef platforms enclosing a central lagoon. Passages provide free connection between the lagoon and waters of the surrounding ocean and inner sea. Open atolls are large structures ranging from 290 to 3,790 km<sup>2</sup> in area, that contain numerous lagoonal reefs and collectively account for 99.5% of all Maldivian reefs. A striking feature of the open atolls is the presence of faros, ring-shaped coral reefs located within broader atoll lagoons. Globally faros are scarce, yet they are abundant in the Maldives where their formation has yet to be resolved. *Closed atolls* have a near-continuous reef rim that enclose their lagoons, and have limited number of passages connecting the lagoon and surrounding oceanic water. There are only five closed atolls in the archipelago, which are much smaller in area than open atolls, ranging from 47 to 143 km<sup>2</sup>.

Four oceanic reef platforms also occur in the archipelago. These reef platforms are individual reefs that emerge from the inner sea or ocean basin and have no structural connection with neighboring atolls. Oceanic reef

platforms are small in area ranging from 4.4 to 10.2 km<sup>2</sup> and have no lagoon that connects to the open ocean. Vegetated islands occupy a large proportion (16–50%) of the reef platforms.

### Latitudinal gradients in atoll characteristics and processes

The physical characteristics of atolls in the Maldives show marked spatial variations along the north-south gradient (Figure 2). Northern atolls are characterized by a heavily dissected atoll reef rim, numerous lagoonal patch reefs and faros, and moderate lagoon depths (40–50 m). Reef islands are located on the peripheral and lagoonal patch reefs. Toward the south, atolls are characterized by more continuous atoll reef rims, a higher proportion of peripheral reef rim containing islands, deeper lagoons (70–80 m), and fewer lagoonal patch reefs.

Latitudinal variations in atoll morphology have been attributed to broad north-south gradients in climate and oceanographic conditions. Annual rainfall reduces from south to north along the archipelago (Figure 2). Over the longer-term this rainfall gradient has influenced solutional lowering of lagoons during Quaternary glacial periods. The archipelago is subject to monsoon conditions that switch from the west to northeast in a predictable fashion and influence wave and current patterns. The intensity of oscillating monsoon conditions increases to the north. In contrast, incident wave energy reduces in magnitude in the northerly direction. This energy gradient influences contemporary coral reef growth and island building processes.

### Reef ecology and biodiversity

The central Indian Ocean location of the Maldives places the archipelago close to the mid-point between the reef faunas of the east and west margins of the ocean basin.

**Maldives, Figure 2** Configuration of the Maldives archipelago, central Indian Ocean showing atoll types, names, latitudinal gradients in climate, oceanography, physical atoll characteristics, and coral species diversity.

This geographic position and the fact that the faunal characteristics of the Maldives reefs have close affinities with the Indonesian high diversity reefs and east African reefs is indicative of the archipelago's important role as a biogeographic stepping stone in the so-called "Chagos stricture." As a consequence, the Maldives has high coral diversity with approximately 250 species of scleractinian corals recorded (Pichon and Benzoni, 2007; Wallace and Zahir, 2007). There are also more than 1,200 reef and reef

associated fish species (Rajasuriya et al., 2004). Of note, coral diversity increases southward along the archipelago.

The health of the Maldivian reefs is of critical importance for the maintenance of land, provision of resources (fisheries and aggregates) and economic earnings (tourism). The reef systems are vulnerable to the impact of anthropogenic stresses and global environmental change. Of note, the Indian Ocean-wide bleaching event of 1998 is estimated to have killed upward of 90% of living coral. This observation is based on the monitoring of limited shallow water reef locations (Rajasuriya et al., 2004). Despite localized coral recovery, global climate change and associated sea level rise, increased ocean temperatures and ocean acidification all pose severe threats to reef health in the near future.

### Reef islands

The Maldives contains 1,190 reef islands perched on top of reef surfaces, 200 of which are inhabited. The islands provide the only living space for the Maldivian population of approximately 330,000. Islands are found on peripheral and lagoonal reefs with larger islands located on the peripheral rims of closed atolls. Composed entirely of carbonate sand and gravels derived from the surrounding reef, the islands are typically small and have a mean elevation of less than 1 m above sea level.

Detailed reconstructions of island formation show that the islands are mid-Holocene in age, forming as reefs reached the latter stage of vertical growth through the infill of shallow lagoons (Kench et al., 2005, Figure 3). A major phase of island building occurred 5,500–4,000 years ago across infilled lagoons with islands remaining relatively stable over the past 3,500 years. Following the phase of island building the outer reef has continued to grow, in final stages of catch-up, forming a moat around island shorelines. Although islands are composed largely of skeletal materials derived from the surrounding reef, cemented sediments can occur on the perimeter of islands (beachrock) and in the island core (cay sandstones and phosphate rocks). These lithified sediments indicate a degree of stability to the island core.

The reef islands have been found to exhibit a high degree of short-term variability in response to seasonal climate patterns and extreme events. Island shorelines exhibit rapid morphological adjustments in response to monsoonal reversals in wind and wave patterns (Kench and Brander, 2006). Situated outside the zone of cyclone-genesis, the archipelago and its islands are not subject to extreme storms. However, the archipelago was affected by the passage of tsunami waves as a consequence of the December 2004 Sumatran tsunami. While this event promoted a small amount of island erosion, tsunami waves inundated islands and allowed the transfer of sediments from beaches to island surfaces. This process of overwash was able to vertically build the margins of reef islands by up to 0.3 m providing further

**Maldives, Figure 3** Summary model of the formation of reef platform islands in the Maldives (after Kench et al., 2005).

evidence that the reef islands are morphologically dynamic features on reef surfaces (Kench et al., 2006).

### Summary

Located in the central Indian Ocean the Maldives is one of the largest and most geologically complex mid-ocean atoll chains in the world. The archipelago possesses high biological diversity, a unique geological history, and contains

a diverse range of reef structures and atoll types. The reefs are also host to a large number of vegetated reef islands. However, despite the aerial extent and unique aspects of reef and island diversity, structure and evolution, the Maldives remain one of the least studied reef systems in the world.

## MANGROVE ISLANDS

Norman C. Duke  
 University of Queensland, Brisbane, QLD, Australia

### Definition

“Mangrove islands” is a descriptive term applied usually to overwash banks or outcrops vegetated notably by mangrove plants (cp. Woodroffe, 2002). Considering the geological definition of islands, mangrove islands are atypical since they lack a terrestrial land mass surrounded by water. In the absence of mangrove plants, the base geomorphic feature would be described as a mud bank or sand cay. Therefore, it is the mangroves themselves that give mangrove islands their island-like appearance. The term is sometimes applied more broadly, however, to include other “low” islands with relatively small terrestrial parts amongst the mangroves.

Mangrove islands are a distinct type of island where the bulk of land area, if not all, is below tidal high water. Since mangrove islands depend on mangrove presence, their occurrence is restricted, as are mangroves, to the tropics and subtropics where sea temperatures rarely drop below 20°C, except in Australia and New Zealand (see *Mangroves*). In addition, the substrate of mangrove islands varies widely, including banks of fine estuarine mud, peat, sheltered sandy berms, rocky outcrops, and coral reef enclaves (e.g., see, Hopley, 1982; Duke et al., 1998; Macintyre et al., 2004). While mangroves favor soft sediments and nutrients in sheltered conditions, they can be

very adaptable, clinging tenaciously to hard or soft substrate in periodically exposed locations.

The biodiversity and structural complexity of vegetation on mangrove islands is influenced by global and regional factors (Duke et al., 1998). Overall, mangrove assemblages are comprised chiefly of downstream marine species: in the Indo-West Pacific (see Duke and Larkum, 2008) – *Aegialitis annulata*, *Avicennia marina*, *Bruguiera gymnorhiza*, *Lumnitzera racemosa*, *Osbornia octodonta*, *Pemphis acidula*, *Rhizophora stylosa*, *Rhizophora mucronata*; and in the Atlantic East Pacific (see Tomlinson, 1986) – *Avicennia germinans*, *Conocarpus erectus*, *Laguncularia racemosa*, *Rhizophora mangle*. Specific diversity depends on terrigenous catchment and annual rainfall, reflecting the importance of fresh water. In general, the larger the catchment water supply, the greater the number of mangrove species. So, larger islands often have greater numbers of mangrove species.

There are two predominant types of mangrove islands, as distinct from continental or oceanic islands. Mangrove islands are influenced by sea level, substrate type, and geomorphic setting, to form as either: (1) reefal mangrove islands based on carbonate or peat sediments (Hopley, 1982; Macintyre et al., 2004), clear waters, and low nutrients; or (2) river mouth mangrove islands (Duke et al., 2005) based on fine terrigenous sediments, turbid waters, and runoff nutrients. Both settings are characterized by active processes where over time the tidal banks are continually formed, eroded, and reformed. Reefal mangrove islands form when mangroves grow on coral reef flats or behind shingle ramparts. Low energy conditions may arise within exposed locations. On Australia’s Great Barrier Reef, “low wooded islands” with mangroves (Hopley, 1982), like Low Isles (Figure 1), often occur behind shingle ramparts on windward, southeastern shores of reefs. Mangrove islands form Montgomery Island in northern Western Australia, and they show that tidal range can be extreme, to 10 m. Overall, the height of mangrove stands on coral reefs is usually modest to low, below 5 m. River mouth mangrove islands form when mangroves occupy depositional banks downstream in the mouths of river-influenced estuaries. Low energy conditions occur during seasonal lulls in river flow and storms. Mangroves readily colonize fine deltaic sediments, rich in organic matter, washed in nutrient-loaded river runoff. The height of resulting mangrove trees is maximal, in some cases attaining 50 m; for example, at the mouth of the Mahe River, Darien, Pacific coast of Panama, and Central America. Because these mangrove islands are formed from riverine sediments, their number and size have expanded greatly following the clearing and disturbance of catchment vegetation, as seen in the Fitzroy River estuary northeastern Australia (Duke et al., 2005; see Figure 2).

Mangrove islands provide valuable structure and habitat, plus areas of respite and refuge, for key groups of

**Mangrove Islands, Figure 1** Expanding mangrove island on the coral reef of Low Isles, northeastern Australia, in 2008 – home to threatened Torres Strait Pigeons.

**Mangrove Islands, Figure 2** Mangrove islands double in area over the last three decades in the river mouth of the Fitzroy River, northeastern Australia, in 2004.

displaced coastal fauna, including: insects, fish, crustaceans, molluscs, birds, flying foxes, and other bats. In northeastern Australia, river mouth mangrove islands are the last refuge for flying fox colonies (Hall and Richards, 2000). In the same region, Torres Strait pigeons take refuge on the reefal mangrove island at Low Isles (Crome, 1975; Frank and Jell, 2006).

## MANGROVES

Norman C. Duke  
University of Queensland, Brisbane, QLD, Australia

### Synonyms

Mangrove forest; Mangrove swamp; Mangrove trees; Sea trees; Tidal forest; Tidal swamp; Tidal wetland

### Definition

**Mangroves.** A tidal habitat comprised of salt-tolerant trees and shrubs. Comparable to rainforests, mangroves have a mixture of plant types. Sometimes the habitat is called a tidal forest or a mangrove forest to distinguish it from the trees that are also called mangroves.

**Mangrove.** A tree, shrub, palm, or ground fern, generally exceeding 0.5 m in height, that normally grows above mean sea level in the intertidal zone of marine coastal environments and estuarine margins.

**Tidal salt marsh.** Small shrubs or herbaceous plants, generally less than 0.5 m in height, that normally grow above mean sea level in the intertidal zone of marine coastal environments and estuarine margins.

**Tidal salt pan.** Flat areas of fine sediments lacking macrophyte vegetation above mean sea level in the intertidal zone of marine coastal environments and estuarine margins.

**Tidal wetlands.** The combination of mangroves, tidal salt marsh, as salt pan, as habitats distinctly occurring between mean sea level and the highest tides. In arid and cooler settings, mangroves share this tidal niche, or are replaced with

diminutive halophyte cousins, the tidal saltmarsh, and flat salt pan expanses with their remarkable microalgal carpet.

### Introduction

Mangroves are one of the world's dominant coastal ecosystems comprised chiefly of flowering trees and shrubs uniquely adapted to marine and estuarine tidal conditions (Tomlinson, 1986; Duke, 1992; Hogarth, 1999; Saenger, 2002; FAO, 2007). They form distinctly vegetated and often densely structured habitat of verdant closed canopies (Figure 1) cloaking coastal margins and estuaries of equatorial, tropical, and subtropical regions around the world (Spalding et al., 1997). Mangroves are well known for their morphological and physiological adaptations coping with salt, saturated soils, and regular tidal inundation, notably with specialized attributes like: exposed breathing roots above ground, extra stem support structures (Figure 2), salt-excreting leaves, low water potentials and high intracellular salt concentrations to maintain favorable water relations in saline environments, and viviparous water-dispersed propagules (Figure 3).

Mangroves have acknowledged roles in coastal productivity and connectivity (Mumby et al., 2004), often supporting high biodiversity and biomass not possible otherwise. Mangrove ecosystems are key sources of coastal primary production with complex trophic linkages (Robertson et al., 1992), as nursery and breeding sites of marine and arboreal life (Figure 4), and as physical shelter and a buffer from episodic severe storms, river flows, and large waves.

In tropical waters, mangrove stands are often sandwiched between two of the world's iconic ecosystems of coral reefs and tropical rainforests. Biota-structured ecosystems, like these, play a unique role in coastal ecosystem processes via a combination of well-developed linkages, coupled with transient biota uniquely adapted to unusual and often dramatic physico-chemical gradients. Linked and dependent relationships developed over millennia have become vital to the survival of each biome. Colonial corals flourish in shallow warm seas of coasts where mangroves buffer and protect them from land runoff. Mangroves absorb unwanted nutrients and turbid waters stabilizing otherwise smothering water-borne sediments and depositional shorelines. These specialized plant assemblages provide important ecosystem services along with additional acknowledged roles of highly productive habitat and nursery sites. The consequences in disturbing these habitats is likely to have unexpected and far-reaching impacts on neighboring ecosystems and dependent biota (Duke et al., 2007).

### Uniquely mangrove origins and vulnerability

Mangroves are a unique ecological assemblage (Duke et al., 1998), remarkable for their relatively small number of widely distributed flowering plants – evolved mostly post-Cretaceous over the last 60–100 million years. The relatively recent evolution of these plants may explain

**Mangroves, Figure 1** Sinuous channels and tidal wetlands of Missionary Bay, northeastern Australia. Amongst the wide mangrove zones are bare saltpans with saltmarsh patches.

**Mangroves, Figure 2** A forest of exposed, above-ground stilt roots of *Rhizophora apiculata*, Daintree River estuary, northeastern Australia.

**Mangroves, Figure 3** Mature, viviparous propagules of a *Bruguiera gymnorhiza* tree, near Dumbea, New Caledonia.

their comparatively low diversity, but this feature is arguably also related to the harsh environmental conditions defining the niche. Today's mangrove flora includes representatives of at least 21 plant families, testament to the

adaptive success of various phylogenetic lineages venturing into the intertidal zone from upland rainforest ancestors. This small group of highly specialized plants tap rich estuarine nutrients with characteristically shallow

**Mangroves, Figure 4** A cormorant makes use of an eroding edge tree of *Sonneratia caseolaris*, in the upper Daintree River estuary, northeastern Australia.

arrays of below-ground roots bearing distinctively vascular, air-breathing anatomy. Specialized above-ground roots and buttresses further provide exposed air-breathing surfaces and physical support, as well as significant habitat amongst their structure – a characteristic shared with adjacent upland forests and reefal corals.

Ancestral mangrove plants are believed to have reinvaded marine environments in multiple episodes from diverse angiosperm lineages culminating in today's mangrove flora (also Saenger, 2002). Their appearance and evolution appears constrained by key functional attributes essential to their survival in saline, inundated settings where isotonic extremes, desiccation, and hydrologic exposure combine as uniquely harsh constraints on organisms living in the tidal zone, and estuaries. The land–sea interface is a dynamic environment, where subtle changes in climate, sea level, sediment, and nutrient inputs have dramatic consequences for the distribution and health of mangroves. Adding to these, direct human disturbance of mangroves include: eutrophication, dredging/filling, overfishing, and sedimentation. The combined pressures, coupled with global climate change and sea level rise, have led to many healthy mangrove areas becoming endangered communities (Duke et al., 2007). Various rehabilitation projects have shown further that it is extremely difficult to achieve effective, large-scale restoration. Urgent protective measures need to be implemented to avoid further mangroves losses and further degradation of coastal ecosystems.

### Rich and diverse

Mangroves are a diverse group of predominantly tropical trees and shrubs growing in the upper half of the intertidal

zone of coastal areas worldwide (Duke, 1992). They are often mistakenly thought of as a single entity. But, like coral reefs, healthy mangroves are functionally diverse and complex. They also provide essential structure and habitat for a host of marine and intertidal species (Figure 5), comprised of both: residents amongst their dense forest of stems and complex roots, and as visitors with each flooding tide. Mangroves are analogous to tropical rainforests also, where they have foliage canopy habitat for birds, mammals, insects, and other invertebrates. Shared ancestral links underlie many similarities between these plant-structured habitats.

Mangroves are not a genetic entity, but an ecological one (Duke et al., 1998). Mangrove vegetation includes a range of functional forms, including trees, shrubs, a palm, and ground fern. The only plant families comprised exclusively of mangrove taxa are Avicenniaceae and Sonneratiaceae, although this continues to be debated. In Table 1, 77 species of mangrove plants are listed for the world. This number however, is not fixed, and varies with different authors since there are a number of subjective and influential factors, including: doubts surrounding the definition of mangroves; whether to include saltmarsh plants; whether to include mangrove associates; and inconclusive taxonomic description of all taxa.

Amongst the 21 flowering plant genera found in mangroves, there is a relatively high degree of specialization for the tidal wetland habitat. Twelve angiosperm genera are exclusively mangrove while ten others include non-mangrove species. This latter group includes: *Aglaia*, *Barringtonia*, *Cynometra*, *Diospyros*, *Dolichandrone*, *Excoecaria*, *Heritiera*, *Mora*, *Pemphis*, *Tabebuia*, and

**Mangroves, Figure 5** *Terebralia* gastropods devouring a fallen mangrove leaf, near Koumac, New Caledonia.

*Xylocarpus*. For *Pemphis*, this genus has only one upland species located inland as an isolated population on the island of Madagascar. Others show different degrees and types of variation. For instance, distinct hybrids are reported in four genera including *Bruguiera*, *Lumnitzera* (Figure 6), *Sonneratia*, and *Rhizophora* (in Table 1, see species prefixed with “X”). Overall, the diversity of species in these genera is often relatively low, being one or two. These relatively low measures of diversity are believed to be the result of harsh growth conditions present in intertidal habitats. Local and regional environmental factors are believed to play a key role in defining the ecological entity that is mangrove habitat. *Rhizophora* species, the most diverse and dominant genus, often occur at the front of mangroves, fronting the sea or channel, and associated with moderate salinities but not extremes. *Avicennia* species, having a wider salinity tolerance, are notably variable occurring in both frontal and upland stands in the Indo-West Pacific.

### Structural diversity

Mangrove plants characteristically range from trees (like species of *Avicennia* (Figure 7), *Rhizophora* (Figure 2)), to shrubs (species of *Aegiceras*, *Aegialitis*, *Pemphis*, and *Conocarpus*), to the trunkless palm (*Nypa fruticans* (Figure 8)), and ground fern (*Acrostichum*). Trees and shrubs vary further where they might be columnar and erect (*Pelliciera rhizophorae* (Figure 9), *Bruguiera parviflora*), to spreading, sprawling (*Acanthus* spp., *Scyphiphora hydrophyllacea*), and multiple-stemmed

(*Ceriops decandra*). Growth form might also vary within the same species (*Lumnitzera littorea* and *Rhizophora*), having both an erect tree form, and low tangled thicket forms. In general, edge plants (both waterfront and landward) have more lower limbs and foliage, and their stems are laterally sprawling and sinuous, rather than erect and straight. Some species typically form combined closed canopies (*Avicennia marina*, *Rhizophora apiculata*, *Bruguiera parviflora*, *Bruguiera gymnorhiza*, *Camptostemon schultzii*, *Xylocarpus* spp.), while others are commonly found as undercanopy plants beneath the closed canopy (like species of *Aegiceras*, *Cynometra*, *Acanthus*, *Acrostichum*, and *Ceriops decandra*).

Mangroves have notable above-ground breathing roots and shallow below-ground anchoring roots, because their soils are usually saturated and airless. The trees have broad support structures, such as buttresses and sturdy prop roots, because soils are often soft and unconsolidated. Root structures above ground include four types: (1) pneumatophores – pencil-like (*Avicennia* (Figure 7)), erect conical (*Xylocarpus moluccensis*), thinly conical (*Sonneratia alba*), and elongate conical (*Sonneratia caseolaris* (Figure 4) and *Sonneratia lanceolata*); (2) knee roots – thick and knobbly (*Bruguiera*) and thin and wiry (*Lumnitzera littorea*); (3) stilt roots (*Rhizophora* (Figure 2)); and (4) buttresses – sinuous planks (*Xylocarpus granatum*, *Heritiera littoralis*, and *Ceriops* spp., *Pelliciera rhizophorae*), and erect “fins” (*Bruguiera X rhynchopetala*, *Xylocarpus moluccensis*). Roots are used by various fauna, but most notably by burrowing shipworms, mollusks, termites, and crabs.

### Factors influencing mangrove distributions

Mangroves have evolved and flourished in their dynamic setting. While mangroves collectively have specialized morphologies and physiologies, these attributes have limits that vary with individual species. The distributional range of each mangrove species reflects its response to the dominant influencing factors at global, regional, and local scales (Duke et al., 1998).

Where mangroves inhabit tropical and subtropical regions of the world, their presence in higher latitudes is generally constrained by the 20°C winter isotherm in the respective hemispheres (Figure 10). Exceptions to this pattern mostly correspond to the paths of oceanic circulation currents where mangrove distributions are broader on eastern continental margins and more constrained on the west. Present day distribution patterns depend on specialized, water-buoyant propagules of mangroves. Their dispersal is constrained by wide bodies of water and continental land masses. Four major barriers restrict dispersal of warm coastal marine organisms (including mangroves) around the world today, namely: the continents of (1) Africa and Euro-Asia; plus (2) North and South American continents; and the oceans of (3) the North and South Atlantic; plus (4) the eastern Pacific. The relative effectiveness of each of these barriers differ, depending on its

**Mangroves, Table 1** Mangrove species of the world. Families and genera with zero 'Non-mangrove' are exclusively mangrove (modified from Duke et al., 1998)

| Families with mangroves                               | Family relatives of mangrove taxa | Family genera | Mangrove genera                                                                             | Non-mangrove      | Mangrove spp.   | Species of mangroves                                                                                                                                                                                                                                                                                                                                                                                                   |

geological history, dispersal/establishment ability, and the evolutionary appearance of respective species.

Regional distribution patterns of mangroves are further influenced by habitat availability and local environmental factors such as rainfall, estuary size, and tides. In Australia (Duke, 2006), two major environmental factors, temperature and rainfall, largely explain regional distributions where low temperatures limit the latitudinal extent of species – affecting the pool of available species. The relative number of species is also highest in areas of higher rainfall. Species richness declines generally with increasing latitude on north-south coastlines and groupings of islands. In general, species diversity in mangrove stands of equal size is greatest in wet equatorial areas. However,

where rainfall is comparable, species diversity is higher in longer estuaries with larger catchments. The influence of rainfall, therefore, not only comes from rain falling directly on mangrove stands, but also as it influences runoff volume from upstream catchments.

At the local scale, individual mangrove species usually occupy only part of an estuary from sea mouth to tidal limit upstream (Duke et al., 1998). Species generally display a preferred estuarine range based on the overall salinity tolerance. For instance, species like *Avicennia marina*, *Rhizophora stylosa*, and *Sonneratia alba* commonly occur in downstream locations. By comparison, *Rhizophora mucronata*, *Sonneratia caseolaris*, and *Bruguiera sexangula* are found upstream in larger,

freshwater-dominated estuaries. Furthermore, at this local scale, respective species occupy distinct parts of the tidal profile above mean sea level. Characteristic zonation bands of different mangrove assemblages indicate the

pronounced influences of inundation frequency and tidal elevation. For example, species like *Avicennia integra*, and *Sonneratia alba* commonly occupy low intertidal positions. By comparison, *Heritiera littoralis*, *Xylocarpus granatum*, and *Lumnitzera racemosa* are found in high intertidal positions. Some species, such as *Avicennia*

the full impact of global climate change and sea level rise begin to take effect.

## Conclusion

Mangroves and tidal wetlands are essential to the sustainability of highly productive natural coastal environments. However, these ecosystems and their dependant biota (Figures 4, 5, and 9) are under serious threat from the escalation this century of large-scale land clearing and conversion of coastal forested wetlands (including mangroves) with the development of coastal lands for agricultural, aquaculture, port, and urban and industrial use (Field, 1995; Duke et al., 2007). In populated areas, key coastal rivers have become little more than drains transporting eroded mud and effluent to settle in downstream estuarine reaches, as well as in shallow embayments and inshore coral reefs. Remaining mangroves have become depauperate, poorly functional vestiges with relatively low resilience. Where healthy, mangrove-lined estuaries had once offered respite and critical dampening of land runoff, in recent years these bastions of coastal buffering and filtering – dubbed “coastal kidneys” – are not responding well to expanding human activities. Efforts to remediate these impacts is being undertaken in many ways with international and regional partnerships, but more is needed as

## MARIANA ISLANDS, CORAL REEF GEOLOGY

Bernhard Riegl  
 Nova Southeastern University, Dania, FL, USA

### Definition

The Mariana Islands are an arch of volcanic islands stretching ~500 miles from Guam to Uracas. Coral reefs occur only in the volcanically inactive southern part (Figure 1). Most of the human population lives on Guam and Saipan and the political organization is split into the U.S. Territory of Guam and the Commonwealth of the Northern Mariana Islands.

The Marianas are part of the Izu-Bonin-Mariana (IBM) arc system, stretching ~2,800 km from Japan to south of Guam. Modern reef building occurs exclusively in the southern Marianas from Guam to Farallon de Medinilla (Figure 1). Corals also occur in the northern arc but no extensive framework production is reported, likely due to a combination of high latitude and relative tectonic instability. In the southern Marianas, temperatures are tropical and ideal for reef-building organisms. Mean annual air temperatures in Guam are 27°C, with ~6°C variations between daily maxima and minima (Figure 2). Relative humidity ranges 65–80% by day and 85–100% by night (Mink and Vacher, 1997). Long-term annual SST means vary between 28°C and 29°C. Tinian has a mean tidal range of 45 cm and a spring tide range of 65 cm (Doan et al., 1960). Rainfall averages at Guam 85–115 in./year (Gingerich, 2003), at Tinian 43–97 in./year (Gingerich, 2002), and at Saipan 34–145 in./year (Carruth, 2003). Wet and dry seasons are well developed with ~70% of total annual rainfall from July–December. Seasonally pulsed rainfall in combination with steep slopes, lateritic soils and deforestation led to runoff and

sedimentation problems on coral reefs (Wolanski et al., 2003, 2004). The Marianas are influenced by the ENSO, and coral records indicate an ~0.75°C warming over the past two centuries (Asami et al., 2005).

### Holocene coral reefs in the southern Marianas

Two major Holocene reef-building episodes are known in the southern Marianas. An early Holocene episode is found in the Merizo (Guam), Milencatan (Rota) and Tanapag (Saipan) Limestones, and the modern reef (Siegrist et al., 1984b). Present-day coral frameworks are mostly narrow and of the fringing type, their morphology often clearly influenced by underlying morphology. In Guam, many small bays are reef-fringed with rivers entering. In such cases, reefs are discontinuous at the rivermouths and increase in thickness and coral cover away from the rivers (Wolanski et al., 2003, 2004). Two notable exemptions to the general pattern of narrow fringing reefs hugging the islands' shorelines exist in Cocos Lagoon (Guam) and Tanapag Lagoon (Saipan), where barrier reefs occur. Development of these lagoons is structurally controlled. Additionally, fringing reefs are developed along the shorelines inside the lagoons (Emery, 1962; Randall, 1979). Also Tinian had a small section of barrier reef that was filled and dredged into a port during World War II.

Four distinct coral habitats (Figure 3), of which only one involves an actively growing reef, occur in the Marianas (Randall, 1985):

- Habitat I consists of *in situ* reef frameworks, with well-developed buttress and channel system (Pagan, Anatahan, Saipan, Aguijan, Rota, Guam).
- Habitat II occurs among volcanic boulders, *in situ* frameworks are absent or only thin veneers (Pagan, Guguan, Anatahan).
- Habitat III exists primarily between old limestone rocks and boulders, *in situ* frameworks are absent (Aguijan).
- Habitat IV occurs along limestone slopes with few boulders, *in situ* frameworks are absent (Saipan, Rota, Guam).

Underlying, and determining the position of late Holocene reef growth are the early Holocene Merizo Limestone (also called “2 m limestone”) on Guam, the Milencatan Limestone on Rota, and the Tanapag Limestone on Saipan. These limestones represent the first phase of reef building in the early Holocene from the post-Wisconsin transgression through the mid-Holocene highstand at ~4,000 year B.P. (before present). They contain beautifully preserved, emergent reef facies in the low supratidal to shallow subtidal and are exposed to about 2–4 m. The emergence of these early Holocene reefs is likely due to tectonic factors (Kayanne et al., 1993; Siegrist and Randall, 1992). Thickness on Guam varies between 5 and 1 m (Siegrist and Randall, 1992). The limestones are coral-dominated and contain virtually all genera that are found in the modern reefs. Growth history on Rota is as follows (Bell and Siegrist, 1988): at 5,500 year B.P. sea level flooded an older, bioclastic facies of the already

**Mariana Islands, Coral Reef Geology, Figure 1** The Mariana Islands, consisting politically of Guam and the Commonwealth of the Northern Mariana Islands, the westernmost territories of the USA.

existing Milencatan Limestone and corals settled on preexisting highs about 80 m behind today's reef margin. Between 5,500 and 4,700 year B.P. corals accreted primarily under rising sea-level conditions and produced high buttresses dominated by corymbose *Acropora* and thick algal crusts. Large *Porites* mounds occurred in protected areas. Around 4,700 year B.P. sea-level rise slowed and

the reefs caught up to the surface (then around +2.5 to 3 m above present sea level; Bell and Siegrist, 1988). Maximum sea level was at ~4,200 year B.P. on Rota and Guam (Kayanne et al., 1993; Pirazzoli and Montaggioni, 1988; Dickinson, 2000). Coral frameworks were then encrusted by digitate coralline algae, which Bell and Siegrist (1988) and Kayanne et al. (1993) interpret as

shallow, relatively high-energy facies, that can still be found in the same area today. Between 4,700 and 2,900 yr B.P. sea level fell, exposing the buttresses, and by 2,850 year B.P. corals settled on the present reef flat and the algal ridge began to develop (Figure 4). A total of 45 species, which still occur in the area, are recorded in the Merizo Limestone (Siegrist et al., 1984a; Randall et al., 1984). The dominant corals were corymbose *Acropora* which fueled the rapid growth and aggradation of the reefs. Similar facies were also described from Rota (Bell and Siegrist, 1988): (1) coral framestone facies of corymbose *Acropora* (primarily *A. humilis*; Kayanne et al., 1993) and in leeward settings of *Porites* mounds, considered to be the catch-up phase of reef growth; (2) algal bindstone facies, which are interpreted as the keep-up algal ridge; and (3) detrital facies at the leeward margin of the reef. High-magnesium cements were common besides aragonite cements.

On Guam and Rota, the early Holocene fringing reef (Merizo Limestone on Guam and Milancatan Limestone on Rota) displaced later Holocene reef growth seaward (Kayanne et al., 1993). Early Holocene limestones are well eroded, in particular, in the softer landward, detrital facies behind the corymbose coral facies (Siegrist et al., 1984a), in which deep lagoons can develop. The present-day reef frequently grows in form of well-developed groove-and-spur buttresses. Also the Merizo and Milencatan reefs had well-developed buttresses and it is unclear whether these reflect forcing by antecedent topography and/or wave

energy. Morphology in deeper water frequently is also highly convoluted and in many areas it is evident that the modern reef is forced into its shape.

There are not only similarities in morphology between the early and late Holocene reefs, but also in the distribution and composition of the primary calcareous reef-builders. The same coral species, as listed by Siegrist and Randall (1985) and Randall et al. (1984), for the early Holocene occur today. Modern buttresses on the reef slope are primarily built by corymbose *Acropora* and deeper on the reef slope or in more sheltered areas, large *Porites*- or *Goniastrea*-built buttresses occur. Shallowest and highest energy parts of the reef edge, when not occupied by calcareous algae, show local dominance by *Pocillopora*. The shallowest reef environments in the Merizo and the present-day reefs are covered by a densely calcified algal ridge. Landward of this algal ridge, another zone of corymbose *Acropora* can be found. In lagoons that are eroded into the Merizo or Milancatan Limestone, typically good growth of *Heliopora coerulea* is found in well-drained areas, large stands of open-arborescent *Acropora* occur alongside *Porites* micro-atolls.

A similar zonation is found across the lagoons of Saipan and Guam. The biotic zonation described by Cloud (1959) at Tanapag lagoon is still recognizable despite significant reduction in space covered by corals and sea grasses (Houk and van Woesik, 2008). A reef slope with variable coral cover and groove-and-spurs abuts a well-cemented reef crest that slopes lagoonward and is

**Mariana Islands, Coral Reef Geology, Figure 4** Stages of Holocene reef growth on Guam from Randall and Siegrist (1988). It is clearly visible how strongly the morphology of present-day reef growth is determined by early Holocene reef growth.

densely overgrown with massive corals and corymbose *Acropora*. Areas with large thickets of *Acropora formosa* still occur but cover is dramatically reduced since the 1940s (about 20% of the lagoon shifted from coral and sea grass cover to sand, Houk and van Woesik, 2008). Toward the center of the lagoon, coral growth becomes increasingly sparse as cover by sandy sediment increases. Rocky outcrops with low coral cover and increasingly high

algal cover toward the land as well as small patch reefs occur irregularly in the lagoon. Dense sea grass beds have also been reduced in size (Houk and van Woesik, 2008).

#### General geology of the southern Marianas – volcanics and limestones

Guam, at the southwestern end of the West Mariana Ridge, was volcanically active from 32 to 20 Ma

(= million years) and 9 to 5 Ma (Reagan and Meijer, 1984). Rifting of the West Mariana Ridge created the Mariana Trough and the Mariana Ridge. Volcanic activity resumed ~1.3 Ma in the active, northern, ridge. The main volcanic basement of Guam resulted from the first volcanic phase and is evidenced in the middle Eocene Facpi Formation (~200 m thick boninite lavas with some limestone infills) and the Eocene to early Oligocene Alutom Formation (~400 m thick, tuffaceous shales, sandstones, volcanic breccias, lapilli conglomerates, pillow lavas, tubidites, some calcareous shales in the Mahlac member, and some coral-rich floats, Schlanger, 1964). Serious carbonate sedimentation began in the upper Oligocene/lower Miocene as Maemong Limestone, a member of the Umatac Formation which is of shallow-water origin and consists of mud- to wackestones with coral (*Porites* and *Acropora*) rudstones and intermixed volcanic detritus. Reefal organisms such as corals, *Tridacna*, *Halimeda*, and crustose algae are common, but *ex situ* and no reef edifice is known. This episode represents a shallowing with carbonate precipitation around three volcanic highs on Guam. The Miocene Bonya Limestone contains deeper-water facies with reef coral and coralline algae detritus but no reefs are preserved, so deposition was likely on a seaward slope between volcanic cones. The Miocene Alifan Limestone contains mudstones that grade to sparry packstones with well-preserved reef fauna and flora (*Porites*, *Acropora*, and *Halimeda*). The smallest limestone unit on Guam is the Tortinian and Pontian Janum Limestone consisting of deep fore-reef to basinal facies (Siegrist and Randall, 1992). The Mio/Pliocene Barrigada Limestone is a chalky foraminiferal-algal wackestone with some corals (*Porites*, and *Astraeopora*). While essentially all limestones show reefal fauna among their components, no Miocene reefs crop out in Guam or anywhere in the Mariana Islands (Siegrist and Randall, 1992).

The most widely distributed limestone is the Plio-Pleistocene Mariana Limestone, the dominant carbonate on Guam, Rota, Aguijan, Tinian, and Farallon de Medinilla (Siegrist and Randall, 1992; Randall, 1995) and also of great importance on Saipan. It contains well-developed reefal and peri-reefal facies. On Guam, it can reach a thickness of 175 m. Reef margin facies generally crop out as the most seaward facies and coincide often with the edges of terraces. Rocks are coralline and coralgal boundstones, coarse grainstones, packstones, and wackestones. Branching and massive corals occur *in situ* and in growth position and Siegrist and Randall (1992) report a rich fauna, reminiscent of the situation in modern reefs (*Acropora*, *Favia*, *Goniastrea*, *Leptoria*, *Platygyra*, *Pocillopora*, *Porites*, *Stylophora*, *Symphylia*, and *Turbinaria*). Detrital facies are common and contain benthic foraminifera, corals, mollusks, oysters, snails, and *Halimeda*. The Mariana Limestone has thoroughly altered porosity and mineralogy and displays many karst features (Siegrist and Randall, 1992).

Rota shares many rock units with Guam but is primarily (>90%) covered by carbonates, mainly Mariana

Limestone (Carruth, 2005; Figure 5). Near the shoreline, exposures of the Milencatan Limestone occur (Sugawara, 1934; Kayanne et al., 1993 refer to it as Milencatan while Bell and Siegrist (1988) refer to it as Mirakattan Limestone), which are an important sea-level indicator (Easton et al., 1978; Randall and Siegrist, 1988; Bell and Siegrist, 1988; Siegrist and Randall, 1992; Kayanne et al., 1993; Dickinson, 2000).

Saipan, the largest of the CNMI (48 sq. miles), consists of an andesitic-dacitic volcanic core (Sankakuyama Formation) overlain by sandstones, conglomerates, and breccias (Hagman, Desinyama, Fina Sisu Formations) which are capped by limestones covering about 95% of the island's surface (Figure 5). Volcanism on Saipan probably ceased in the Oligocene, after which marine deposition produced thick limestone sequences.

The Matansa Limestone is an upper Eocene carbonate bank deposit (Cloud et al., 1956). Saipan's center is covered by the early Miocene Tagpochau Limestone, a complex of calcareous clastic rocks. Saipan's eastern side is Pliocene Mariana Limestone, as found on Guam and Rota. It is reefal with argillaceous rubbly facies (Carruth, 2003) and differs from the Tagpochau Limestone in the abundance of corals and the modern aspect of its fossil assemblage. Mariana Limestone does not occur along the entire western coast but disappears under Tanapag lagoon (Figure 5). Thus, the structural control of the lagoon rim (= barrier reef) is probably determined by the course of the Mariana Limestone. Lagoon and the coastal lowlands seaward of the Tagpochau Limestone are probably fill, overlying the Mariana Limestone. The Tanapag Limestone is a Pleistocene to Holocene raised reef limestone, well indurated and porous with well-preserved coral heads and mollusk shells (Cloud et al., 1956). It formed as fringing reefs on an emerging surface with maximum thickness <20 m. Its younger, Holocene, parts are correlative to the Merizo Limestone of Guam and the Milencatan Limestone of Rota (Dickinson, 2000) and occur along the steep eastern shoreline of Saipan.

In Tinian, which is situated 5 km south of Saipan, the oldest rocks belong to the Eocene Tinian Pyroclastics (Doan et al., 1960), exposed in the central highlands and the island's southern section (Figure 5). The rest of Tinian is covered by limestones. The same Miocene Tagpochau Limestone as on Saipan is exposed on about 15% of the island. Pliocene Mariana Limestone covers the majority of Tinian (~80% of its surface and thickens from 0 to 150 m in all directions from near the Tinian Pyroclastics; Doan et al., 1960; Gingerich, 2002). Like on Saipan, the limestones on Tinian are heavily faulted and karstified. Recent alluvium and colluvium reaches thicknesses up to 13 m.

Farallon de Medinilla is the northernmost of the calcareous Marianas and is also mostly covered by Mariana Limestone (Randall, 1995). North of Farallon de Medinilla, the Mariana Islands bear no limestone caps and are volcanically active. This active island arc stretches from Anatahan to Uracas (Meijer and Reagan, 1981).

**Mariana Islands, Coral Reef Geology, Figure 5** (a) Surfacial geology of Guam (Modified from Gingerich [2002]). (b) Early Miocene volcanic highs in relation to Miocene carbonates show that the latter formed primarily as ramp facies on and around the volcanic cones (Siegrist and Randall, 1992). (c) Surfacial geology of Saipan (Modified after Carruth [2003]). (d) Surfacial geology of Tinian (Modified after Doan et al. [1960] and Gingerich [2002]).

## Conclusions

- Reef building in the Mariana Islands is confined to the inactive southern Arc from Guam to Farallon de Medinilla.
- The dominant coral reef type in the Marianas is fringing reefs, with barrier reefs only at Guam (Cocos Lagoon) and Saipan (Tanapag Lagoon).
- The northern Marianas are volcanically active and corals occur there, but tectonic instability and volcanic activity have precluded reef building.
- Reef building in the southern Marianas likely dates back to the Miocene, but no reef edifice has yet been found (corals and reefal fragments only).
- Late Holocene reef building in the southern Marianas is constrained by the presence of an early Holocene reef episode (Merizo Limestone on Guam, Milencattan Limestone on Rota, and younger part of Tanapag Limestone on Saipan) that clearly shows a mid-Holocene sea-level overshoot.

## MASS EXTINCTIONS, ANOXIC EVENTS AND OCEAN ACIDIFICATION

---

John E. N. Veron  
 Townsville, QLD, Australia

### Introduction

The five great mass extinction events that have greatly influenced paths of evolution of life on Earth have attracted a wide range of speculation about original causes and ultimate effects. In this context, reefs are among the most widely studied of marine communities, partly because carbonate platforms are so enduring, but also because the fossil record of corals is relatively well known in terms of abundance and distribution. The marine tropics in general and reef taxa have been particularly targeted in mass extinctions. In each case, they have taken many millions of years to recover, intervals of time known as “reef gaps.” Many authors have speculated on the causes of mass extinctions and reef gaps, the outcome being a wide array of hypotheses involving climatic upheavals of both terrestrial and extraterrestrial origin. This article reviews these proposals and examines them in the light of the biology of extant corals and their Pleistocene history.

### Mass extinctions, corals, and reef gaps

Mass extinction events are characterized by fundamental changes in plant and animal diversity as many high-level taxonomic groups go extinct over the same geological time interval. They are also characterized by very slow recovery, led by the evolution of new species rather than recolonization by survivors.

The five great mass extinction events occurred at widely spaced intervals, each at or near the end of major divisions in Earth history. Of these, extinctions at the Permian and Cretaceous were so profound that they respectively mark the end of the Palaeozoic and Mesozoic eras. However, present interest in mass extinctions is not so much in their geological timing, but in their cause, for they illustrate outcomes of extreme environmental upheavals and are thus worst-case scenarios of climate change.

Mass extinctions are usually perceived as dramatic catastrophes inflicted on an otherwise peaceful Earth, but this is

not the case. There were actually many minor or background extinction events at other times that left clear marks in the fossil record – no fewer than 27, according to a particularly detailed study (Raup and Sepkoski, 1986; Sepkoski, 1995). Although not global, some background extinctions were just as catastrophic as mass extinctions for particular ecosystems or particular places, and many had major impacts on coral reefs. Reefs, more than any other major type of ecosystem, leave a geological record that tracks such events (e.g., Sepkoski, 1995; Wood, 1999; Stanley, 2001). On an Earth history scale, this record does not show a process of gradual evolutionary development or improvement, but rather a stop-start response to a succession of environmental upheavals. Reefs are actually uncommon throughout the Phanerozoic and appear to have a “boom or bust” existence (Veron, 2008a and Kiessling, 2009). Environmental conditions that lead to reef proliferation are generally well understood; it is those which lead to their demise that are addressed below.

### The end Ordovician mass extinction

The first great mass extinction “event” took place at the end of the Ordovician, a time when, according to the fossil record, 26% of all families and 60% of all genera of both terrestrial and marine life worldwide were exterminated (Hallam and Wignall, 1997). This extinction occurred at the end of a period of high mean global temperatures, probably caused by global greenhouse stability, a condition that seems to have prevailed since the end of Cambrian 70 million years earlier. The extinction, however, was not just one “event.” It took place over a very long time span, perhaps several million years, and appears to have been the cumulative outcome of a succession of disasters. Possible causes that have been suggested include major fluctuations in sea level, multiple short-lived polar glaciations, and changes in ocean temperature, circulation, and chemistry. The extinction was particularly disastrous and long lasting for reefs (Webby, 1992; Copper, 2001). Extreme levels of carbon dioxide have been recently implicated (Berner, 2006). Although some individual rugose and tabulate coral taxa survived, living reefs disappeared from the face of the Earth and did not reappear for another 4–6 million years, long after the climate had returned to preextinction conditions. This is the first true “reef gap,” meaning a gap in the geological record of reefs.

### The late Devonian mass extinction

The Late Silurian to Late Devonian period – 75 million years or so of more or less global greenhouse conditions with high temperatures set between ice ages – probably included all-time peaks of Palaeozoic reef development (Copper, 2002). Sea levels were mostly high, so that seas flooded extensive areas of continents, forming epicontinental seas. However, despite the apparent proliferation of reefs, their development was intermittent, with major periods of worldwide expansion, especially during the

Middle Silurian to Late Devonian interspersed with periods of apparent collapse (Copper, 1994).

The world's Devonian reefs may have been every bit as well formed and biologically diverse as today's reefs and, with an estimated area of  $5 \times 10^6$  km<sup>2</sup> (including inter-reef areas), may have been as much as twice as extensive (Copper, 1994). The Late Devonian mass extinction, like that at the end of the Ordovician, has been linked to multiple causes. Many bolides may have struck the Earth around this time (McLaren and Goodfellow, 1990 and others), although this is unlikely to be linked to the extinction (reviewed by Racki, 2005). A precipitous drop in atmospheric carbon dioxide owing to uptake by vascular plants, low global temperatures, and wildly fluctuating sea levels have all been blamed (Copper, 2001). The extinctions appear to have varied geographically, although they primarily affected marine life: reef development ceased almost completely. Some corals and stromatoporoid sponges lived on, but there was no recovery for the vast coral-sponge reef-building communities anywhere in the world. Instead, the survivors were microbes. These continued to build carbonate structures, but these have none of the characteristics of "reef" or "coral reefs" built by skeleton-secreting organisms.

Reefs – although still not structures comparable to today's coral reefs – existed sporadically during much of the Carboniferous and Permian – through times of oscillating temperatures and sea levels, including the periodic development of polar ice caps. Some of these reefs, especially those of the Late Permian, were very extensive. Their fossil content indicates that they were exceptionally diverse relative to their forebears, for they contained extensive arrays of all of the major marine groups, especially molluscs, echinoderms, and crustaceans, as well as rugose and tabulate corals.

### The end Permian mass extinction

The fossil record of the end Permian mass extinction reveals a staggering loss of life: 82% of all genera and perhaps 80–95% of all marine species went extinct (Sepkowski, 1995, 2002; Erwin, 2006). All rugose and tabulate corals and most other calcifying organisms ceased to exist. The cause of this catastrophe was one of the foremost questions in palaeontology a century ago, and it remains so today. At one point or another, wildly fluctuating temperatures in response to sharp increases in atmospheric carbon dioxide, acid rain, and lack of oxygen in shallow waters after protracted times of plenty have all been held responsible. The oceans are widely believed to have turned anoxic and to have contained free hydrogen sulphide (Wood, 1999). Recent studies using biomarkers and isotopic data (Grice et al., 2005) are particularly revealing, one study suggesting that hydrogen sulphide generated by bacteria in deoxygenated oceans was so abundant that they released enough hydrogen sulphide to drive terrestrial extinctions (Ward, 2008). Other studies suggest that a sudden release of methane occurred at this

time (Ryskin, 2003; Erwin, 2006). Recently, a comprehensive palaeophysiological study clearly implicates carbon dioxide (Knoll et al., 2007), perhaps associated with the Siberian Traps, the biggest volcanic outpouring of all time. Whatever the cause (reviewed by Knoll et al., 2007), the impact on reefs was sudden by geological standards and devastating. Some members of most marine phyla survived, yet reefs did not reappear for about 10 million years, the greatest hiatus in reef building in all of Earth history. What emerged in the Middle Triassic was the Scleractinia in place of their Palaeozoic predecessors. There is much in common between the ancient reefs of the mid-Palaeozoic and the first scleractinian reefs that took their place, not so much in the animals that built them, but in the stop-start nature of their intervals of growth, their biodiversity, and the sheer size of the structures they formed.

### The end Triassic mass extinction

For 20 million years Triassic scleractinian corals, in concert with calcifying sponges and algae, went on to build some of the most spectacular reefs of all time. There was another substantial extinction of corals early in the Late Triassic, followed by a brief interval of dramatic recovery. Then, once again, the Earth plunged into a full-scale mass extinction. The end Triassic mass extinction (Stanley, 1988, 2001) – the fourth in the history of reefs – is estimated to have claimed about half of all marine invertebrates. The main taxa affected were conodonts (all), ammonites (almost all), and bivalves and gastropods (over half of all species). One-third of all scleractinian families went extinct and fewer than 25% of all genera are known to have survived (Beauvais, 1984). Nevertheless, this mass extinction, like its predecessors, was not only marine; perhaps 80% of all land quadrupeds also went extinct. The cause, again, has been much debated without a clear outcome (Wood, 1999; Flügel and Senowbari-Daryan, 2001). Atmospheric carbon dioxide reached extreme levels for the Mesozoic (perhaps eight times today's level) (Hautmann, 2004; Hautmann et al., 2008), and high greenhouse temperatures certainly resulted. Short-term sea-level fluctuations and various changes in ocean chemistry have been implicated by several palaeontologists, although none gives convincing evidence. The extinction was relatively abrupt (in geological time), making the reason for it particularly obscure. Whatever the cause, reefs again remained rare or absent throughout the world for a vast amount of time, perhaps 6–8 million years.

### The end Cretaceous mass extinction (K/T)

K/T has been extensively studied because of its indelible association with the demise of the dinosaurs. However, many well-known animal groups besides the dinosaurs went extinct at the K/T boundary. Virtually no large land animals survived. Plants were also greatly affected, although this is less clearly documented. Once again

tropical marine life was decimated, including a high proportion of calcifying organisms. All remaining ammonites and belemnites went extinct, as did a high percentage of bivalves, gastropods, and echinoids, as well as almost all Foraminifera. Many other unicellular organisms including radiolarians were also severely affected. However, most other major taxa – including freshwater fish, amphibians, turtles, crocodiles, snakes, and lizards – appear to have been almost unaffected, as were placental mammals.

Criteria used in extant coral taxonomy suggest that one-third of all families and 70% of all genera went completely extinct. Of the extant families, the Faviidae retained six of its original 16 genera; the others survived with only one or two. At least that is what the fossil record appears to say Veron (1995). However, that record is poor (Rosen and Turnšek, 1989; Kiessling, 2001) partly because sea levels were high during most of the Cretaceous and reefs were eroded away as the seas receded. Importantly, no branching corals appear to have survived, thus the habitats maintained by branching corals – those that provide shelter for algae-grazing fish – would have completely disappeared. On a taxonomic level, there are differences of opinion based primarily on what are considered to be valid records. Veron (1995) found that azooxanthellate corals were affected to the same degree as zooxanthellate corals, whereas Kiessling and Baron-Szabo (2004) on other criteria found that they were less affected. There are also differing views as to whether there was a reef gap or not. What is beyond dispute is that the fossil record is poor and few details been gleaned from it (Rosen, 2000).

Globally averaged atmospheric temperatures at the time of K/T have been estimated to be 6–14°C higher than at present (Barron, 1983), ranging from a few degrees' difference at the equator to as much as 20–40°C at the poles (Barron and Washington, 1985). Estimates of carbon dioxide levels vary greatly; however, the data for K/T are more reliable than those for more ancient extinctions. By the end Cretaceous carbon dioxide levels were at least five times, and perhaps as much as ten times, those of today (Berner, 1994; Tajika, 1999; Gale, 2000; Johnson et al., 2002).

A bolide hitting the Earth near the Yucatán Peninsula of southeast Mexico was widely thought to have caused the K/T extinctions (Alvarez et al., 1980). This theory, however, is highly controversial: over 2,000 books and articles were published about it within a decade of the original publication (Glen, 1990); the consensus now being that the bolide was not the primary cause of the extinction. The impact itself and the outpourings of the shock-induced volcanoes are widely believed to have created a stratospheric dust cloud that would have plunged the whole of the Earth into a cold, interminable night. Certainly acid rain (including nitric acid generated from heat-induced fusion of nitrogen and oxygen), high levels of carbon dioxide released from the impact site and from volcanic eruptions everywhere, and high concentrations of methane released from continental slopes would have combined to create intense greenhouse warming.

However, the timing of the ultimate extinction of different animal groups, the time taken for many to go extinct, and the age of the bolide debris do not correlate well. Some animal taxa became extinct within an apparently brief period, whereas others, including the dinosaurs, took hundreds of thousands of years, and their decline started long before the bolide's impact.

### Causes of mass extinctions

Extrapolations from today's knowledge of coral biology to past environments must be cautiously made, especially as the Scleractinia of today have been in existence for only two mass extinctions (the end Triassic and K/T). However, just as a number of physical parameters have remained effectively constant throughout the Phanerozoic, some physiological processes, while they may vary in detail over time, would in general have been applicable to the Scleractinia throughout their existence.

The causes of mass extinctions are divisible into two classes; those that do not involve the carbon cycle and those that do (Veron, 2008a, b).

### Causes independent of the carbon cycle

Reef development has three prerequisites: (1) corals (and/or other calcifying organisms) must exist in environments that are favorable for calcification, (2) the resulting calcium carbonate must be consolidated into reefs, and (3) the rate of erosion must be less than the rate of accretion. Mass extinctions and reef gaps might occur whenever calcification is decreased, or there is a breakdown in the mechanisms of consolidation, or there are factors that increase the erosion or dissolution of calcium carbonate. In the case of K/T, where there was a simultaneous extinction of both zooxanthellate and azooxanthellate coral species, any explanation of extinction must span wide depth ranges as well as broad spatial scales.

#### *Direct physical destruction from bolides*

A bolide many kilometers across could possibly cause massive destruction of reefs along the exposed side of an area the size of a continent; however, it beggars belief that such an effect, from a single point source, could envelop the whole Earth (Toon et al., 1997). Nor is there any way that azooxanthellate species would be equally affected or that surviving reef corals would take millions of years to recommence reef building. Be that as it may, the Earth has several large and well-known craters (13 of which date to the early Mesozoic or later) (Jablonski, 1986), and many studies, motivated by the discovery of the K/T bolide, have sought to establish these as the primary cause of extinction events. Yet credible links have not emerged (Rothschild and Lister, 2003). Indirect effects of bolides are another matter.

#### *"Nuclear Winter" induced by dust clouds*

Bolides are presumably capable of creating dust clouds that may have enveloped the Earth for weeks or months, creating devastating darkness and (for terrestrial life) cold.

Survival estimates for corals under conditions of very low light vary from death in just a few weeks to survival of at least parts of colonies for six months or more. Significantly, this strongly suggests that, if today's reef-building species were suddenly subjected to conditions of very low light for periods of years rather than weeks or months, 99% of species would go extinct. No such extinction has ever happened to the Scleractinia. The proportion of zooxanthellate corals that went extinct at K/T is not on its own sufficient to explain the end of reef building or the reef gap that followed: (1) Many taxa that survived, including members of the Poritidae and Faviidae, are among the best reef builders (Veron, 1995). (2) Azooxanthellate taxa fared no better than zooxanthellate taxa. (3) The K/T mass extinction caused a much higher rate of extinction in corals than in many other photosynthetic organisms, notably terrestrial vascular plants, which would have been more vulnerable to prolonged darkness.

From a biological point of view, it can be concluded that very low light, even if maintained for months, is exceedingly unlikely to have been the principal cause of the K/T mass extinction event. The dust cloud created by the K/T bolide would also have caused atmospheric temperatures to plunge, but only for as long as the cloud persisted. The thermal inertia of the oceans would have protected marine environments from significant temperature change.

#### *Sea-level changes*

The major sea-level changes throughout Earth's history have been due to plate tectonics. These are very different from the sea-level changes that occurred during the Pleistocene, primarily in being much slower and of immensely longer duration. During the last glacial cycle, the sea level dropped 130 m (Lambeck and Chappell, 2001; Siddall et al., 2003). This fall is more than the depth range of all but a few deepwater zooxanthellate corals, which means that almost all corals had to relocate. Throughout the Pleistocene, such falls were repeated many times, yet only about 10% of all corals went extinct over this entire interval (Veron and Kelly, 1988). This is no more than a background extinction rate. Thus sea-level changes of any kind, let alone those resulting from tectonic movements, can be discounted as a primary cause of coral species extinctions.

#### *Loss of area during sea-level regression*

Loss of reef area during sea-level changes of the past has been suggested as a cause of coral extinctions, but the Pleistocene history of modern corals offers a number of reasons why this would not be so. There were major losses of reef area during the last glacial cycles; however, these had no significant effect on today's coral diversity. At the opposite extreme, small areas may have most of the species complement of an entire province. The great dispersal capabilities of corals would ensure that recolonization would take place swiftly from surviving niches. Area loss is thus highly unlikely to have been a primary cause of any

extinction. Furthermore, azooxanthellate species would have been unaffected by a loss of reef area.

#### *Loss of biodiversity as a cause of reef gaps*

Reef building does not depend on high species diversity. Many of the corals that survived K/T belonged to genera well able to build reefs in the absence of any other coral species. We can therefore discount loss of biodiversity as a primary cause of reef gaps.

It has also been suggested that reefs do not reestablish until peak evolution rates of new species are reached (Jablonski, 1986). Although this may have been true after some mass extinctions (there is no evidence either way), it was certainly not the case after K/T as coral diversity remained low long after widespread reef building had reestablished.

#### *Low temperatures*

Conceptually, low temperatures could explain reef gaps and coral extinctions, but the data available for global temperatures give no credence to this. During the K/T extinction, ocean temperatures were at or above, rather than below, present levels. Furthermore, the suite of reef-building genera that survived indicates no selection for cold tolerance. Nor does low temperature explain why azooxanthellate species were lost. Even during a full glacial cycle, the world's oceans cool only around 6°C, and less than this at the equator. Although temperature reductions of this extent would be enough to contract the latitudinal range of species today, such a decrease could not have initiated extinctions in equatorial regions on the scale of any mass extinction.

#### *High temperatures*

Elevated temperatures can cause mass bleaching of corals, creating widespread devastation when reef ecosystems become so degraded that they are taken over by macroalgae and bacterial slime. However, mass bleaching only occurs in zooxanthellate organisms as it is due to an overproduction of photosynthetic oxygen. Over geological time, corals growing under such conditions have the evolutionary option of avoiding the issue by becoming azooxanthellate. In such circumstances, any reduced capacity for calcification would be in part offset by the effects of temperature. Furthermore, a mass extinction from temperature would require that such temperatures extend to highest latitudes. This would never have been possible, even under the most extreme conditions. High temperatures cannot explain the extent or global nature of mass extinction events, nor can they account for the species that survived K/T, nor the loss of azooxanthellate taxa.

#### *Salinity*

Corals, and by extension reefs, are adversely affected by low salinity and low salinity may well have been a major cause of regional extinctions at various times, especially in partly landlocked regions such as the epicontinental

seas of the Super-Tethys and North Africa during the Cretaceous. However, it is inconceivable that any continental landmass could hold enough fresh water to cause a global mass extinction.

#### *Disease and toxins*

There is strong evidence today that stresses such as mass bleaching, hyposaline influxes, and a wide range of other ecological imbalances can greatly increase the incidence of diseases in corals. Combinations of stresses from high temperature, high light levels, and disease might lead to major regional losses of corals for as long as those stresses persist. These would have to be very widespread and affect deepwater and nearshore corals equally. The Earth has no toxins in such quantities, nor any that can exist both on land and in the oceans.

#### *Extraterrestrial events*

Extraterrestrial events apart from bolides have commonly been suggested as causal factors in extinctions. Episodes of ultraviolet or cosmic radiation from solar flares or supernovas (which may be capable of stripping away the ozone layer, allowing high levels of ultraviolet radiation to reach terrestrial life) can be discounted as causes of mass extinctions because the deep ocean would have shielded bottom-dwelling communities, and these were not shielded. There is also the often-mentioned finding that extinctions follow a 26-million-year periodicity, implying an overriding extraterrestrial “supercycle” of unknown origin. The database of fossils referred to above presents an avalanche of statistics in support of this conclusion (Raup and Sepkoski, 1986); nevertheless, although this long periodicity does not look entirely random, it does not look distinctly cyclical either, so this concept remains enigmatic and without a plausible mechanism.

#### **Links between mass extinctions and the carbon cycle**

If the above causes of mass extinctions and reef gaps are discounted as primary factors, there remains an array of further possibilities that have one aspect in common: they are either part of the carbon cycle or closely linked to it. This is hardly surprising, for of all the great matter cycles of the Earth, the carbon cycle is by far the most important.

The chemical impacts discussed below are all directly or indirectly linked to the carbon cycle. Severe environmental degradation can occur rapidly in response to bolide impacts and some geological events such as larva flows (traps) or supervolcanoes. They may also occur in response to slower processes created by gases release from volcanic chains as a result of seafloor spreading and other tectonic movements. Although slow, these processes may lead to relatively abrupt extinctions through cumulative outcomes and synergies.

Importantly, small changes in the concentration of atmospheric gases can lead to major changes in global environments, potentially affecting both marine and terrestrial life. These gases include major components of

our atmosphere, notably oxygen and water vapor, as well as those that are only present in trace amounts. The latter include the gases that control the atmosphere's greenhouse warming of which carbon dioxide and methane being the most important.

Peripheral links to the carbon cycle are considered here first.

#### *Acid rain*

High levels of atmospheric carbon dioxide produce carbonic acid, and high levels of sulphur dioxide produce sulphuric acid. These substances, together with nitrous oxide from industry and the draining of tropical marshlands, are the main sources of acid rain today. Carbon dioxide and sulphur dioxide are released in massive amounts from some volcanoes, traps (notably the Deccan Traps of India at the time of K/T) and other sources, both terrestrial and marine, both to be ultimately neutralized by ocean buffers. Although sulphur dioxide and nitrous oxide do not contain carbon, by the time their products reach the oceans they do, and thus they are inextricably linked to the carbon cycle. It is not quantitatively possible for acid rain to be a primary cause of an extinction event; however, acid rain may well have acted in synergy with other causes to create extreme environmental degradation.

#### *Hydrogen sulphide*

Hydrogen sulphide is another gas released in large quantities into the oceans and atmosphere from volcanoes or from sulphur-rich geysers and the like. It also has biological origins, which is why it regularly occurs in anoxic waters of all types, ranging from aquaria to atoll lagoons. As with sulphur dioxide, although it does not contain carbon, it is inextricably linked to the carbon cycle and could, in terms of quantity, have been a significant contributor to an environmental upheaval in synergy with other gases.

#### *Oxygen and anoxia*

In a nitrogen-dominated atmosphere, oxygen and carbon dioxide have an additive relationship, an increase or decrease of the one creating a parallel effect in the other, all else being equal. However, all else may sometimes not be equal, and there may have been conditions, perhaps the end Permian and K/T, where ocean anoxia may have been created by primary productivity decrease (through phytoplankton depletion) as a result of acidification. By this simple mechanism, high levels of atmospheric carbon dioxide can work synergistically with low levels of atmospheric oxygen to create ocean anoxia. Whether or not this has actually happened is not known.

#### *Methane*

Methane from geological sources, plant respiration, and some animal life exists in minute amounts in the atmosphere (currently 1.8 ppm). However, it occurs in much greater quantities in permafrost, in tropical marshlands, and in vast quantities as icelike solids (clathrates or hydrates) that are stable only under pressure and at low

temperatures on continental shelves. The volume of these solids is unknown, although it is of the same order of magnitude as the Earth's total quantity of fossil fuels. Methane leaks into the ocean and atmosphere naturally, for example, as marsh gas. However, if it were released into the atmosphere in substantial quantities, perhaps as a result of a bolide impact or a buoyancy change in the methane ice (for which there are many possible causes), there could be serious environmental consequences. It would have a major greenhouse effect (methane has 22 times the potency of an equal volume of carbon dioxide) and would also be converted to carbon dioxide by microbes and chemical oxidation, causing the same adverse effects characteristic of high levels of carbon dioxide.

#### *Carbon dioxide*

Both increasing and decreasing carbon dioxide levels have been proposed as major contributors to mass extinction events in the past. Over geological time scales, carbon dioxide has varied from levels much lower than the 387 ppm of today up to perhaps ten times today's level (depending on the reliability of studies of a small number of fossil soils and whether or not results from single points in time are representative of longer time intervals). The effects of high levels of atmospheric carbon dioxide are pursued below.

#### *Ocean chemistry and pH*

This subject can only reliably be assessed via the chemistry of contemporary oceans. Increased atmospheric carbon dioxide leads to greater amounts of the gas dissolving in the oceans, which directly reduces pH. This, in turn, alters the proportions of different forms of inorganic carbon ( $\text{CO}_2$ ,  $\text{H}_2\text{CO}_3$ ,  $\text{HCO}_3^-$ , and  $\text{CO}_3^{2-}$ ) in the ocean (Buddemeier et al., 2004; Kleypas and Langdon, 2006). Increasing the concentration of carbon dioxide in the ocean alters the proportion of the other three forms of carbon. Calcifying organisms use carbonate and/or bicarbonate ions to build skeletons, and thus a decrease in their availability slows the calcification process. The proportions of each of these carbon components are sensitive to temperature and pressure, and thus to latitude and depth.

Acidification affects zooxanthellate corals and most azooxanthellate corals by different paths. The former are sensitive to acidification of surface waters by atmospheric carbon dioxide directly; the latter are sensitive to having their depth range reduced by shallowing of  $\Omega_{\text{aragonite}}$ . These surface and deep layers directly influence each other at high latitudes where temperature gradients are weak and mixing occurs relatively easily. However, they are well separated in the warm tropics, especially at the thermocline, and interact primarily via the sinking of carbonate skeletons of surface-dwelling plankton.

Shallow oceans are currently supersaturated with carbonates, allowing zooxanthellate corals to calcify. However, as  $\Omega_{\text{aragonite}}$  decreases, calcification requires increasing amounts of energy. The same applies to azooxanthellate corals, although here the process depends

on the depth of the aragonite saturation horizon, which, in turn, varies with temperature as well as chemistry: as changes in water temperature and chemistry cause the horizon to rise, the depth range of azooxanthellate corals shallows.

#### *Acidification*

The dependence of calcareous algae on high-magnesium calcite, the most soluble of all calcium carbonate skeletons, makes them particularly vulnerable to acidification (Kiessling et al. 2008, Veron, 2008b). Since these algae are critical to reef consolidation, their removal would, in the past, reduce the net accretion of reefs before the rate of coral calcification became limiting. With further decrease in pH, aragonitic organisms including Scleractinia would become increasingly affected, further tipping the balance in favor of reef erosion. Since acidification from elevated atmospheric carbon dioxide affects oceans on a global scale, the effects on reefs would be worldwide, although influences from temperature and surface water mixing would create local variations both geographically and with depth. In equatorial regions, adverse changes in carbonate/bicarbonate ion availability as a result of decreasing pH would be exacerbated by lack of mixing between the warm, shallow, carbon dioxide-enhanced surface layers, and the buffers of cool, deeper ocean water. Acidification could thus have a devastating effect on reef development, leading initially to widespread inhibition of reef growth and eventually to reef erosion and dissolution.

The first impact will be on azooxanthellate taxa, which would be to displace them from deeper oceans as the  $\Omega_{\text{aragonite}}$  horizon shallows. This effect is greatest at high latitudes (Guinotte et al., 2003; Turley et al., 2007). Two recent studies point toward acidification as the primary cause of coral extinctions and the reef gaps, despite deficiencies in the fossil record. (1) Late Cretaceous azooxanthellate corals of the caryophylliid genus *Coelosmia* have been found to have calcitic skeletons rather than skeletons of the more soluble aragonite as have today's Scleractinia (Stolarski et al., 2007). (2) Two Mediterranean corals, *Oculina patagonica* and *Madracis pharensis* which were placed in acidified aquaria gradually lost their skeletons, then regrew them after being returned to normal seawater (Fine and Tchernov, 2007).

Unlike the alternative causes of extinctions noted above, acidification can explain why both azooxanthellate and zooxanthellate species were affected at the time of K/T. It can also explain the loss of reefs both locally and globally, as well as account for the existence of long-lasting reef gaps. Although acidification may be difficult to initiate because of ocean buffers, once achieved it will persist as long as atmospheric carbon dioxide remains high. Furthermore, the oceans would remain acidified for tens of thousand years after carbon dioxide levels had declined, that being the time required for normal alkalinity to be restored. This would be an interval long enough for corals to initiate an evolutionary recovery. Under such

a recovery sequence, reef gaps in the past of millions of years would be a plausible consequence, depending primarily on the endurance of atmospheric carbon dioxide and the rate of evolutionary accommodation to it.

#### *Low levels of carbon dioxide*

Low levels of carbon dioxide may result in low levels of photosynthesis, leading to low levels of oxygen and eventually ocean anoxia. This might have triggered the Late Devonian mass extinction event; the evidence is inconclusive.

### Conclusions

The foregoing discussion argues that ocean acidification and anoxia as a mechanism explains mass extinctions better than other mechanisms that have been offered. However, studies of ancient environments also suggest that similar atmospheric carbon dioxide levels may have occurred at times when reefs actually proliferated rather than declined. One explanation may lie in the interpretation of information from ancient times for carbon dioxide data are very uncertain for most of geological time as it is based on a small number of point samples from widely different geological intervals. In contrast, as seen in ice core records and contemporary measurements, carbon dioxide levels can fluctuate substantially over intervals as short as millennia. Many possibilities present themselves. (1) Reefs may not have proliferated at all during carbon dioxide highs; they only appear to have survived because they were able to resume growth when levels fell (the boom or bust observation made above). (2) The high apparent carbon dioxide levels of ancient times may be an artifact of a lack of data and measuring methods, which currently produce very conflicting results. (3) Corals and other taxa may have become partly or completely askeletal (as noted above) during times of adverse ocean chemistry. (4) Corals may have had calcitic skeletons during such times and the calcifying process may have been more physiologically isolated from ocean pH than it now is. These options can only be guessed; there may have been many aspects of coral biology that allowed ancient corals to tolerate water chemistries that are lethal to today's taxa.

Although these deliberations about possible causes of mass extinction events have highlighted acidification as the most probable cause of both coral extinctions and reef gaps, it would be misleading to consider this as the only cause. Indeed, all mass extinctions appear to be the outcome of several different influences acting synergistically. Acidification may well have been a primary mechanism by which marine ecosystems were affected; however, low light, bleaching, deteriorating water quality owing to acid rain or anoxia, mechanical damage, and disease would all have played their parts. Although the time frames of bolides do not always fit the facts as a singular cause of extinction, bolides or traps or volcanic chains may have created severely adverse conditions that became "the straw that broke the camel's back."

## MAYOR, ALFRED GOLDSBOROUGH (1868–1922)

---

Lester D. Stephens  
 University of Georgia, Athens, GA, USA

Born in Frederick, Maryland, on 16 April 1868, Alfred Goldsborough Mayer (spelling changed to Mayor in 1918) was the son of Alfred Marshall Mayer, a noted American physicist. Although an excellent student of mathematics and physics, young Alfred preferred zoology as his field of study. However, as his strong-minded father wanted his son to pursue a career in the physical sciences, Alfred majored in engineering at the Stevens Institute of Technology, in Hoboken, New Jersey, from which he graduated in 1889. He began advanced work in physics soon thereafter, but decided to enter the graduate program in zoology at Harvard University in 1892, where he came to the attention of Alexander Agassiz, a prominent marine zoologist and director of Harvard's Museum of Comparative Zoology (MCZ). Agassiz soon placed Mayor in charge of the MCZ's division of coelenterates and other radiate species.

Mayor collected specimens for the MCZ in various locations on the east coast of America and around the Dry Tortugas, in the Gulf of Mexico. Between 1896 and 1900, he also accompanied Agassiz on three major collecting expeditions in the South Pacific Ocean. Mayor received the Ph.D. degree in 1896, but continued in his position at the MCZ until 1900, when he left to become curator of zoology in the Brooklyn Museum.

In 1903, the Carnegie Institution of Washington (CIW) approved Mayor's proposal for establishing a tropical marine laboratory on Loggerhead Key, in the Dry Tortugas, and made him director of the new station, which opened in 1904. During the early years of the Laboratory, Mayor worked mainly on jellyfish taxonomy, and, in 1910, completed the monumental three-volume work titled *Medusae of the World*. Two years later, he published *Ctenophores of the Atlantic Coast of North Atlantic*, a standard work on the comb jellies.

Influenced by the studies of the prodigious coral geologist Thomas Wayland Vaughan, who conducted considerable research at the Tortugas Laboratory, Mayor began around 1913 to focus his attention on the stony corals. In the waters of the Florida Keys and later those of the South Pacific, Mayor concentrated on the ecology of coral reefs, and produced a number of pioneering studies on the growth-rate of corals and the effects of temperature, light, water depth, wave action, fresh water, and silt on coral development. In 1917, he began to use a diving helmet to further his studies, thus becoming one of the first biologists to conduct underwater explorations of reefs. Mayor was elected to membership in the National Academy of Sciences in 1916.

By the time of his premature death on 24 June 1922, on Loggerhead Key, Mayor had achieved international acclaim for his pioneering work in jellyfish and comb jelly taxonomy and on coral-reef ecology. A monument in his memory was erected on Loggerhead Key in 1923.

## MEGABLOCKS

Cliff Frohlich, Matthew J. Hornbach,  
Frederick W. Taylor  
John A. and Katherine G. Jackson School of Geosciences,  
University of Texas, Austin, TX, USA

## Synonyms

Boulder or megaboulder deposits; Coral boulders; Coral megablocks; Erratic coral boulders

## Definition

*Megablocks*. Intact blocks or boulders, often composed of coral and occasionally with dimensions of 10 m or greater, situated well apart from (as much as 100–500 m) and sometimes well above (up to 30 m) their original formation sites.

## Introduction

Coral megablocks are large erratic boulders detached from the reefs or paleoreefs where they formed, and presently situated in the surf zone, along the beach, or still further inland. We distinguish megablocks from sea stacks, which are coral formations that may be similar in size and location to megablocks but are still in growth position, attached at their bases. Megablocks as discussed here are also distinct from tectonic segments or arc segments, often described along subduction zones, which are tectonic blocks with horizontal dimensions up to tens of km or greater that undergo coherent lateral or vertical motions distinct from the motions of adjacent blocks or segments. There is also a vast literature describing ice-raftered or glacier-deposited boulders composed of materials other than coral; for example, glacier-transported boulders reported in Tierra del Fuego by Charles Darwin (1842) are still being studied today (Kaplan et al., 2007).

Scientific interest in megablocks, whether composed of coral or otherwise, often focuses on determining the mechanism and timing of their emplacement. Where coral megablocks may have been emplaced by prehistoric storms or tsunami waves, analysis can provide information about potential hazards from natural events too rare to be represented in the historical record.

## Examples

Erratic megablocks often occur near and below sea cliffs. Although the specific mechanism of transport may be uncertain, in most cases a plausible explanation is that the blocks separated from the cliff due to the action of surf, biological activity, earthquakes, or weathering, and subsequently were transported downhill via mass wasting.

However, coral megablocks also occur where sea cliffs are absent, and may lie well above their original sites of formation (Scheffers and Kelletat, 2003). To emplace these, storm or tsunami waves are the most credible mechanism (e.g., Zhao et al., 2009), especially as some such emplacements have occurred historically. The 26 December 2004 Indonesian tsunami deposited hundreds of meter-sized coral boulders in the intertidal zone along Pakarang Cape, Thailand (Goto et al., 2007), including some with estimated weights up to 40 tons (Kelletat et al., 2007). On 27 August 1883 the island of Krakatau in Indonesia experienced a huge explosive eruption; at Anyer beach at a distance of 40 km, this produced a tsunami with a reported height of 36 m that moved coral megablocks distances up to 240 m. The largest transported megablock had a reported volume 317 m<sup>3</sup> and an estimated mass of 600 tons (see picture in Simkin and Fiske, 1983).

A third well-studied historical example of megablock emplacement is on the island of Ishigaki, in the Okinawa group, offshore Japan. Here in April 1771, a tsunami accompanying an earthquake killed some 12,000 island residents and also displaced numerous coral boulders, some with dimension  $\sim 5$  m (Imamura et al., 2008). Controversies surrounding this incident concern (1) whether an earthquake rupture on any regional fault was alone sufficient to generate the tsunami, or whether the earthquake triggered an undersea landslide (Nakamura, 2006); (2) the height of the tsunami, variously reported as 30–85 m, and the geographic extent of its runup; and (3) whether the 1771 tsunami alone emplaced the megablocks, or instead they were emplaced by previous storms or tsunamis and simply moved again in 1771 (Suzuki et al., 2008).

There are no historical records of emplacement for many megablocks. Frohlich et al. (2009) studied coral megaboulders along the western coastline of Tongatapu in the southwest Pacific. The largest stone (see Figure 1) is situated  $\sim 10$  m above present sea level and 130 m from the present shoreline. It is one of seven similar megablocks found along a 3-km arc 100–400 m from the present shoreline. The blocks contain well-preserved corals demonstrating that the stones are no longer in growth position. All these stones are the highest features locally. Frohlich et al. (2009) concluded that these megablocks were emplaced by a tsunami, generated probably by explosive volcanism along the Tofua arc  $\sim 30$  km west of Tongatapu, or possibly by an undersea landslide just offshore. Other examples of

exceptionally large coral megablocks occur in the Bahamas (Hearty, 1997), and in the Tuomotu Islands (Bourrouilh-Le Jan and Talandier, 1985).

### Origin and mechanism of transport: Tsunamis or storms?

In coastal environments, elucidating the circumstances of megablock emplacement provides crucial information about rare but very severe natural hazards, especially as the historical record in many locations covers only the past century or two. However, there is often controversy about whether storms or tsunamis emplaced the megablocks (e.g., Nott, 2004). This is partly because historically documented storms have displaced some rather large boulders, and partly because distinguishing the characteristics of tsunami-emplaced vs storm-emplaced deposits is a still-developing field (Morton et al., 2007). For example, Noormets et al., (2002) describe a 96 ton megablock emplaced by the 1946 tsunami and since twice moved by storm waves on Oahu in Hawaii.

The largest historically documented storm-emplaced stones displaced vertically upward and moved distances exceeding a few meters have average dimensions smaller than  $\sim 5$  m and masses less than 100 tons (Nott, 2004); we conclude that larger megablocks are probably tsunami-emplaced as it is likely that the historical record includes storms having near-maximum possible intensities. Wind speeds, wave heights, and storm surge characteristics correlate roughly with the diameter of the

**Megablocks, Figure 1** A large coral megablock on the island of Tongatapu, southwest Pacific. This block has dimensions of  $15 \text{ m} \times 11 \text{ m} \times 9 \text{ m}$  and sits with its base 10 m above sea level and  $\sim 130$  m from the present shoreline; it is one of seven megablocks that form a group on western Tongatapu.

storm's circulation pattern, and the historical record includes storms such as 1979 typhoon Tip in the western Pacific which had a diameter of 2,200 km (Dunnavan and Diercks, 1980). This is larger than the Gulf of Mexico, the Caribbean, or the Mediterranean; it is difficult to imagine sustaining a significantly larger storm. There has been discussion that sea surface temperatures exceeding 36°C might generate 'hypercanes', storms much stronger than any observed historically (Parks Camp and Montgomery, 2001). However, no one has yet suggested that such conditions occurred within the past several million years.

Tsunamis may be generated by several different natural phenomena, including earthquakes, undersea landslides, subaerial landslides that reach the sea, undersea volcanic eruptions or flank collapses, and meteoroid impacts. Although tsunami hazard analyses focus principally on earthquake-induced tsunamis, the largest tsunami waves are generated by other causes. For example, two of the highest historical tsunami waves were generated by a subaerial landslide (wave runup to 520 m elevation, Lituya Bay, Alaska, 1958; see Mader and Gittings, 2002) and a volcanic eruption (~36 m waves, Krakatau, Indonesia, 1883; see Simkin and Fiske, 1983).

Evaluating megablock occurrence may help quantify hazards and occurrence rates for undersea landslides. This is important because several investigations conclude that giant-to-moderate (100–10 km<sup>3</sup>) submarine slope failures may cause exceptionally large tsunamis (Ward and Day, 2001). Sometimes undersea landslides accompany or are triggered by earthquakes and produce tsunamis much larger and more devastating than those attributable to the earthquake alone (e.g., the 18 November 1929 Grand Banks earthquake; see Fine et al., 2005; and the 17 July 1998 New Guinea earthquake; see Heinrich et al., 2001; Satake and Tanioka, 2003). In many coastal locations even a cursory evaluation of offshore bathymetry demonstrates that undersea landslides have occurred.

### Dating the emplacement of megablocks

During the past 400 ky, sea level has only been at or above its present only during interglacials. Interglacial highstands typically occur at intervals of about 100,000 years and have durations of ~10,000 years. The two most recent highstands are the past 7,000 years and 120–130 ka; thus these are the most plausible times of emplacement for large megablocks presently situated at elevations near or above their sources. Generally the more recent interval is likely because exposed coral limestone dissolves with rainfall, destroying megablocks over time. During subsequent highstands, sea level returns to near the level of paleomegablocks and they are destroyed by bioerosion. And of course, any that were deposited during lower sea levels are now underwater or had sea level pass over them, thereby eroding them and then burying them under new reef growth. When megablocks contain well-preserved corals, <sup>230</sup>Th dating can determine when they

lived and thus constrain an earliest credible time for emplacement.

Where megablocks occur as part of a well-preserved stratigraphic sequence emplaced by a storm or tsunami, this may contain mineral or organic material datable using U-series or <sup>14</sup>C methods. Where megablocks contain identifiable coral species indicating that the blocks are overturned, it may be possible to use <sup>10</sup>Be or <sup>26</sup>Al to estimate how long the upper surface has been exposed (e. g., see Nishizumi et al., 1993).

In some environments where erratic megablocks are situated on a raised coral-reef terrace, they are perched on pedestals that have formed beneath the blocks as the adjacent terrace limestone is dissolved by rainfall solution. Matsukura et al. (2007) describe examples of such perched megablocks found on Kikaijima Island in the Ryukyus; they estimate that the dissolution rate of the unsheltered terrace surface is ~205 mm/ky. As many pedestal heights are ~1.0–1.5 m, they conclude that the megablocks were deposited on a reef flat which emerged and began experiencing dissolution about 6,000 years ago. Although it might seem that measuring pedestal heights would provide an accurate way of dating megablock emplacement, at present this is a subject for additional research as reported dissolution rates vary by two orders of magnitude or more and depend on numerous factors including amount of rainfall, whether or not the block is exposed to both rainfall and sea spray, average temperature, and porosity and composition of the terrace surface.

### How fast the current? How high the wave?

Wherever large erratic megablocks occur, they provoke the question of how strong a current was required to displace them. If they are situated on land, how high was the storm or tsunami wave that moved them?

A physics-based analysis provides some approximate answers to these questions. In classical hydrodynamics, an object of cross sectional area  $A$  in a fluid of density  $\rho_w$  streaming at velocity  $V$  experiences a drag force of  $\frac{1}{2}C_d\rho_wAV^2$ , where  $C_d$  is a dimensionless parameter known as the drag coefficient which is ~1/2 for objects such as smooth spheres. To displace a megablock with dimension  $h_b$  and density  $\rho_b$ , the drag force approximately equals its buoyant weight; thus as its cross section is  $\sim h_b^2$  and its volume is  $\sim h_b^3$ ,

$$\frac{1}{2}C_d\rho_w h_b^2 V^2 > g(\rho_b - \rho_w)h_b^3 \quad (1)$$

and

$$V > \sqrt{\frac{2g}{C_d} \left( \frac{\rho_b}{\rho_w} - 1 \right) h_b} \quad (2)$$

If a wave impacts a shoreline, potential energy stored at the wave crest may be converted to kinetic energy, producing a current as the wave breaks and flows onshore. Estimating the height  $h_w$  of the wave necessary to displace

a boulder depends on various assumptions about the dimensions and hydrodynamic properties of the boulder (e. g., see Nott and Bryant, 2003; Noormets et al., 2004). However, a very crude ‘rule of thumb’ is that

$$h_w > \frac{\rho_b}{\rho_w} h_b; \quad (3)$$

i.e., the height of a wave necessary to displace a boulder of given density and height is approximately proportional to the product of the boulder’s relative density and its linear dimension. This is often an adequate estimate as generally knowledge of the boulder’s hydrodynamic parameters and density  $\rho_b$  (see Spiske et al., 2008) is highly uncertain.

In practice, the interaction of waves and shorelines is highly nonlinear and depends critically on details of the nearshore bathymetry, and thus computer modeling is required to obtain substantially more accurate results (Mader, 2004). Of practical importance is the observation that boulders entrained in a tsunami tend to saltate, tumbling end-over-end rather than sliding, and thus attention to the dimensions and orientations of megablocks may provide information about the direction of the flow that emplaced them (Imamura et al., 2008).

## Summary

Megablocks are erratic coral boulders, some with dimensions as great as 10 m or more, found in and landward of active reef zones. In locations where they can only have been wave-emplaced, they provide important information about the frequency and intensity of rare, very large storms and tsunamis. However, at present identifying the specific characteristics that constrain the features of the waves that emplaced them, or that confirm their origin to be a storm or tsunami, is still a subject of active research.

## Synonyms

[Catastrophic \[sea-level\] rise event](#); [Sea-level jump](#)

## Definition

A meltwater pulse is an acceleration in sea-level rise which results from outbursts of pro- or subglacial meltwater and/or surging of ice-streams into the ocean during ice-sheet disintegration. Radiometric ages of coral-reef drowning and back-stepping indicate that rates of sea-level rise during these meltwater pulses were at least 35 mm/yr and may have been as much as 60 mm/yr, and that these rises persisted for 300–500 years.

## Introduction

Measuring the age and elevation of late Quaternary reef-crest corals has enabled geoscientists to reconstruct the rate and magnitude of relative sea-level rise at several sites

and identify global episodes of rapid sea-level rise that resulted from pulses of meltwater or iceburg discharge during the disintegration of ice sheets (Fairbanks, 1989; Blanchon and Shaw, 1995). These reconstructions show that the rate and magnitude of sea-level jumps were truly astonishing. Coastal and shallow marine ecosystems were inundated by rises of as much as 15 m at rates of up to 60 mm/yr. It is no surprise that understanding their causes and consequences has subsequently become the focus of a large multi-disciplinary research effort with particular emphasis on how they may relate to possible future rapid climate and sea-level change.

## Glacial Termination I (MIS-2)

Pulses in melt-water discharge during the last deglaciation were first reported by Fairbanks (1989) from an analysis of drowned reef-crest sequences cored off the south coast of Barbados. By plotting age/depth data from the reef-crest coral *Acropora palmata* in these cores and correcting them for tectonic uplift (0.34 mm/yr), he reconstructed sea-level rise during the last deglaciation between 17,100 and 7,800 radiocarbon years ago. From this curve, he identified two “exceedingly rapid” rise events separated by a period of reduced melting, and estimated that the first event, melt-water pulse 1a (Mwp-1a), was a rise of 24 m in less than 1,000 years centered at 12,000 radiocarbon years BP, and the second event, melt-water pulse 1b (Mwp-1b), was a rise of 28 m centered at 9,500 radiocarbon years BP. Fairbanks suggested that these rapid-rise events corresponded to the most intense phases of seasonal melt-water discharge during the disintegration of Northern Hemisphere ice-sheets, and estimated discharge rates of 14,000 km<sup>3</sup>/yr and 9500 km<sup>3</sup>/yr, respectively. In later studies, he and co-workers re-dated all samples using more precise <sup>230</sup>Th ages (Bard et al., 1990; Fairbanks et al., 2005) and produced a curve showing that Mwp-1a was centered at 14,000 years, with a period of reduced melting between 13kyrs and 11 kyrs, and Mwp-1b was centered at 11,000 years BP (Figure 1).

However, these meltwater pulses coincided with gaps between cores which led some to argue that they were artifacts resulting from non-uniform uplift, or from the post-growth collapse of reef deposits themselves (see discussion in Broecker, 1990; Bard et al., 1996; Radtke and Schellmann, 2006). To rule out this possibility, evidence of reef-drowning from other areas was required. That evidence was reported by Blanchon and Shaw (1995) who determined that elevations of drowned *A. palmata* reefs in the Caribbean-Atlantic reef province were consistent with the stepped pattern of sea-level rise identified from Barbados. By combining the previously reported coral ages with stratigraphic data, including the positions of *A. palmata* framework, intervening gaps, and the transitional thickness between units, they further constrained the timing, rate, and magnitude of these melt-water pulses and calculated that Mwp-1a was a 13.5 m rise in 290 years centered at 14,200 years, there

**Meltwater Pulses, Figure 1.** Three-step model of post-glacial sea-level rise in the Caribbean. Reconstruction of sea-level older than 8 ka uses uplift-corrected elevation and thickness of back-stepping *A. palmata* reef-crest sequences from Barbados (modified from Fairbanks, 1989; Blanchon and Shaw, 1995) and precise  $^{230}\text{Th}$  ages from corals in those sequences (Peltier and Fairbanks, 2006). Reconstruction of sea level younger than 8 ka is from stratigraphic sequences and calibrated radiocarbon-ages of relict and active Holocene reefs in tectonically stable areas of the Caribbean (Blanchon et al., 2002; Toscano and Macintyre, 2003). The position of mean sea level is constrained by maintaining coral age/elevation data within a 5 m envelope (shaded) which represents the 0–5 m reef-crest habitat depth zone where *A. palmata* forms a monospecific assemblage mixed with its clasts. Outliers are the result of either up-slope transport during storms or, in other areas, result from deeper habitat ranges for reef-crest corals. Correction for continuous uplift of Barbados is assumed to be 0.34 mm/yr but is ignored for quantification of the rate and magnitude of sea-level jumps that caused episodes of reef-crest drowning and back-stepping. Gray boxes show (non-uplift-corrected) age/elevation data gaps between reef-crest framework that are used to calculate minimum rate and magnitude of sea-level jumps; maximum magnitudes are calculated by assuming that sea-level position was 5 m higher than the base of up-slope reef-crest framework (as required by its 5 m depth habitat) and an increment of 5 m is added to the elevation gaps. Caribbean three-step model is contrasted with data from Tahiti, the Huon Peninsula, and the Sunda Shelf.

was a period of reduced melting between 13kyrs and 11 kyrs, and Mwp-1b was a 7.5 m rise in 160 years centered at 11,000 years (Figure 1). They also identified an additional melt-water pulse event at 7,100 radiocarbon

years that drowned early Holocene reefs below the 15 m isobath and led to the initiation of modern reefs above the 10 m isobath. Later calibration of these age data showed that this additional reef-drowning melt-water

pulse was centered at 8,000 calendar years (Toscano and Macintyre, 2003) and produced a rise of 6.5 m in <140 years (Blanchon and Shaw, 1995).

Subsequent attempts to test the 3-step model of Caribbean sea-level rise, and corroborate the existence, timing, and magnitude of melt-water pulses, have only been partially successful. The most successful sea-level reconstruction is from the Sunda Shelf between the Indonesian archipelago and the Vietnam peninsula (Hanebuth et al., 2000). Two core transects between the 126 m and 48 m isobaths recovered a transgressive sequence of organic-rich tidal-flat and mangrove-swamp deposits (Hanebuth and Statteger, 2003). Radiocarbon dating of in-situ organics above the Pleistocene basement allowed the reconstruction of sea level ( $\pm 1$  m) from 21 to 11 kyrs ago. This high-resolution reconstruction showed that Mwp-1a was recorded as a 16 m rise in 300 years starting at 14.6 calendar kyrs ago, almost identical to the rate and magnitude calculated from the Caribbean drowned reefs ( $13.5 \pm 2.5$  m in 290 years; Blanchon and Shaw, 1995). The only difference was the timing: on the Sunda Shelf Mwp-1a occurred 400 years before it did on Barbados (Figure 1). Although there has been considerable argument about which of these is correct (e.g., Weaver et al., 2003; Stanford et al., 2006), the difference in age between these sites may simply be the result of down-slope transport of younger *A. palmata* clasts onto the oldest drowned reef on Barbados seen at the top of core RGF-9 (Figure 1). Such a possibility could easily be tested by dating the lowest section of the up-slope reef (seen at the base of core RGF-12). Down-slope transport would cause an age overlap between the drowned and up-slope reefs.

Less precise reconstructions using corals with larger depth ranges have had more limited success. For example, a single core from the Huon Peninsula of Papua New Guinea recovered an uplifted 52 m thick coral sequence which recorded continuous reef accretion between 11,000 and 7,000 radiocarbon years BP (Chappell and Polach, 1991). All coral samples were later re-dated to obtain more accurate  $^{230}\text{Th}$  ages (Edwards et al., 1993) and corrected for tectonic uplift (1.9 mm/yr). The sea-level curve based on these new data showed a distinct period of reduced melting between 12.3 kyrs and 11.0 kyrs, followed by a clear Mwp-1b centered at 11 kyrs (Figure 1). It was claimed that the period of reduced melting prior to the meltwater pulse was shorter than at Barbados, but corals used to identify sea-level position at Huon have larger depth ranges than *A. palmata* and therefore are not as reliable in pinpointing the precise elevation of sea level (Chappell and Polach 1991). Also, the assumption that uplift was uniform in this highly-active neotectonic terrain cannot be confirmed.

Cores recovered from the modern reef-crest around the more tectonically-stable island of Tahiti found a thicker 90 m sequence of continuous reef accretion back to  $\sim 13,800$   $^{230}\text{Th}$  yrs BP (Bard et al., 1996; Montaggioni et al., 1997). This sequence therefore started accreting

immediately following Mwp-1a implying that its effects in Tahiti were the same as in Barbados, and that a rapid sea-level rise had caused reef drowning and up-slope reef back-stepping (Blanchon, this volume). As in the other records, the coral age/depth data, when corrected for subsidence (0.25 mm/yr) showed possible evidence for a period of reduced melting prior to Mwp-1b, but it was significantly shorter (11.5–11 kyrs) than that in either Barbados or PNG. Interestingly, however, the Tahitian corals consistently plot deeper than those at Barbados, indicating that they may not be as precise at indicating sea level as claimed (Blanchon, 1998). This is supported by two observations: the increase in offset of the Tahiti corals through time, and the pattern of shallowing of the cored reef sequence (Figure 1). Both observations indicate that the reef prograded after Mwp-1a so that, in a vertical core, progressively deeper reef-front corals were encountered through time. In other words, Tahitian cores represent deeper-reef accretion when compared to those in Barbados. New cores collected during the IODP-310 Tahiti Leg, should help determine if this offset is indeed the result of deeper coral growth or a function of differing glacio-isostatic-adjustment histories. One preliminary result so far indicates that Mwp-1a at Tahiti has a similar timing to that identified from the Sunda Shelf at 14.6 ka (Deschamps et al., 2009).

In addition to the deglacial events, evidence for a meltwater pulse at 8 kyrs (Mwp-1c) has also been further supported by additional discoveries of drowned reefs from Grand Cayman, southeast Florida and the Gulf of Carpentaria (Blanchon et al., 2002; Banks et al., 2007; Harris et al., 2008). On the east coast of Grand Cayman, a transect of short cores along the reef-front in 20 m of water recovered a submerged *A. palmata* reef-crest whose surface corals returned  $^{230}\text{Th}$  ages of between 8.9 kyrs and 8.1 kyrs BP (Blanchon et al., 2002). The depth of this drowned reef also corresponded with an intertidal notch on the western shelf at a depth of 18 m and indicated the establishment of an 18-m shoreline between 8.1 cal and 7.6 cal ka. Comparison of the age/depth data between Grand Cayman and other Caribbean islands, indicated a near synchronous demise and back-stepping of *A. palmata* reefs across the Caribbean around 8 kyrs ago in response to a rapid 6-m jump in sea level (Blanchon et al., 2002). But two potential problems with this jump hypothesis have been raised. The first problem was that back-stepping could only be demonstrated by comparing the age of reef drowning in one location with the age of up-slope reef initiation in another. In other words, there were few sites where clear evidence of both drowning and back-stepping had been reported together. That changed recently with the reporting of new age/depth data from an up-slope reef off the southeast Florida shelf (Banks et al., 2007). Combining the calibrated radiocarbon-age data of this new reef with those from an earlier report of an 8 ka old drowned reef further down-slope (Lighty et al., 1978), confirmed that at this site Mwp-1c at 8 kyrs caused the back-stepping of *A. palmata* reef crests 6–7 m up-slope in less than 580 years (Blanchon, this volume).

The second potential problem with the 8 ka jump was the discovery of a deposit of *A. palmata* off Sand Key, Florida, that apparently filled the elevation gap between drowned and back-stepped reefs (Toscano and Lundberg 1998; Figure 1). This deposit developed between 12.5 m and 9 m below present sea level and contained 9–7 ka old corals. In other words, it developed at the same time as the 8 ka old drowned reef reported 4–7 m further down-slope by Lighty et al., (1978). Given that Banks et al., (2007) confirmed that the down-slope reef morphology is directly analogous to that of modern Florida breakwater reefs, this means that Sand Key deposit further up-slope cannot also be a breakwater reef. This objection is supported by the fact that the deposit not only contains age reversals, but an 86 ka old extraformational clast reworked from the underlying foundation. The mismatch in elevation with coeval down-slope reefs, together with the evidence of reworking, clearly indicates that the Sand Key deposit is not of reefal origin but is a coastal boulder-rampart deposited by storms and hurricanes. As noted by Blanchon and Perry (2004), such problems highlight the importance of identifying in-place *A. palmata* reef framework using textural and taphonomic criteria in order to differentiate it from either boulder ramparts deposited up to 5 m above present sea-level, or submerged accumulations which can be deposited in much deeper water.

Until recently, there was scant support for reef drowning related to the 8 kyr Mwp-1c outside the Caribbean (e.g., Bard et al., 1996). But in 2008, Harris et al., reported early Holocene reef development in the Gulf of Carpentaria, northern Australia. Multi-beam sonar and short drill cores demonstrated widespread reef development between 23 m and 33 m water depth starting at 10.5 kys and ceasing by 8 kyrs. Unfortunately, the coral sequences were poorly developed and it is unknown if these reefs grew at sea level or were submerged below it. Their surface elevations however are remarkably consistent over wide areas indicating they were likely breakwater reefs. Evidence for the 8 ka Mwp-1c has also been reported from other sedimentary systems, notably deltas and estuaries (Stanley and Warne 1994; Bratton et al., 2003; Hori and Saito 2007) and isolation basins in glacio-isostatic rebound terranes (Yu et al., 2007).

### Last glaciation (MIS-3)

Reports of meltwater pulses prior to the last deglaciation are more controversial. For example, there have been multiple claims of melt-water pulses during the last Glacial between 19 ka and 65 ka. The first of these is a proposed melt-water pulse at 19 ka which is based on a core transect across the Bonaparte Gulf, in northern Australia between depths of 147 m and 34 m (Yokoyama et al., 2000). These cores recovered shelf and marginal-marine to brackish-water facies based on the foraminiferal and bivalve assemblages, which were used to radiocarbon date the sequence. Using age/depth data of the transition from the low-stand

brackish-water facies into the succeeding marginal-marine facies, it was argued that meter-scale elevation differences between cores was the result of a melt-water pulse centered at 19 cal ka BP. The validity of this sea-level reconstruction, however, has been contested by Shennan and Milne (2003), who highlighted the presence of hiatuses reported in a later study (Yokoyama et al., 2001), inconsistencies between cores, and doubts concerning the depth range of the facies units. As a consequence, the interpretation of a meltwater pulse at 19 kyr is suspect.

The second report of a 19 ka meltwater pulse is from the north-east Irish coast where a presumed fluvial incision was filled by transgressive marine foraminiferal mudstones along a coastal area undergoing active glacio-isostatic uplift (Clark et al., 2004). The uniform age of these deposits and the apparent transgression over a fluvially-incised subaerial surface were interpreted to result from a rapid 10 m rise in sea level at 19 cal ka BP. Unfortunately, alternative interpretations of the origin of the incised valley, such as marine ravinement, cannot be ruled out. In addition, the correction of the ages for marine reservoir has been disputed by Hanebuth et al., (2009). Such problems once again render the interpretation of a meltwater pulse at 19 ka as ambiguous.

Further reports of fully Glacial (MIS-3) stage meltwater pulses have come from the Huon Peninsula. There, the ages of uplifted reef terraces between 30 ka and 65 ka apparently matched rapid climate changes and ice-sheet events seen in Greenland ice and north Atlantic sediment cores (Chappell, 2002). A sea-level reconstruction from these terraces used the thickness and geomorphology of reef-crest and intertidal units to model the relative rate and magnitude of sea-level rise by making assumptions about reef type and accretion rate. Then, these relative rises were used to reconstruct absolute sea-level position using  $^{230}\text{Th}$  ages of the reefs and applying uplift corrections (Figure 2). This preliminary reconstruction showed 5 rapid sea-level-rise events of between 10 m and 20 m within duration of 1–2 ka; the timing of some of these rises coincided with rapid-ice loss events from the Laurentide Ice Sheet, known as Heinrich events (Hemming 2004).

Further dating of the Glacial reef terraces on the Huon Peninsula by Yokoyama et al., (2001) attempted to provide an independent sea-level reconstruction and model glacio-isostatic adjustment (Figure 2). Unfortunately, this new reconstruction conflicted in terms of timing, number, and magnitude of rapid sea-level rise events with the reconstruction of Chappell (2002). This is largely because Yokoyama et al., (2001) ignored the problem of true-age variability (Scholtz and Manginni, 2007) and considered all isotopically-reliable ages to be valid sea-level indicators, despite their lack of stratigraphic consistency. These errors were compounded by making an age-dependant uplift correction for every dated coral, rather than making this correction for a core-group of ages that best represented the time-span of individual reef-crest development. Together these errors led to single outlying ages forming the peaks of rapid sea-level-rise events, and

**Meltwater Pulses, Figure 2.** Three sea-level reconstructions for the Huon Peninsula's Glacial coral-reef terraces (Terraces II and III). Lower reconstruction is based on a model of reef thickness, type, and accretion rate estimates, corrected for uplift using average  $^{230}\text{Th}$  age of individual terraces (Chappell, 2002). Middle reconstruction based on new  $^{230}\text{Th}$  ages (Yokoyama et al., 2001) with each age corrected for uplift. Upper reconstruction is based on correction of all  $^{230}\text{Th}$  ages for open system effects (Thompson and Goldstein, 2005) with each age corrected for uplift. Correcting each age for uplift introduces serious errors and results in single outlying anomalous ages forming the peaks of rapid sea-level-rise events, and neighboring ages from the same reef being placed in different parts of the sea-level curve. In other words, curve position is an artifact of dating which results from true-age variability of samples.

neighbouring ages from the same reef being placed in different parts of the sea-level curve (e.g., ku16 and k13 in Figure 2). In other words, this implies that a single conformable reef unit developed during different stages as

sea level returned to the same position over time. Later, Esat and Yokoyama (2006) claimed that this 'disorderly growth conjecture' was a valid explanation of reef development, rather than addressing the more plausible

explanation that  $^{230}\text{Th}$  ages are difficult to replicate on sub-millennial timescales, as shown by the fact that 50% of ages with pristine isotopic values can have discordant  $^{231}\text{Pa}$  ages (Scholz and Mangini, 2007). In addition, disorderly growth is clearly untenable in conformable reef sequences, given that multiple passes of the shore-face would leave significant stratigraphic evidence of marine erosion and/or subaerial exposure.

The problem of true-age variability in the ages of Yokoyama et al., (2001) was partially addressed by Thompson and Goldstein (2005) who recalculated them to correct for bias introduced by open-system diagenesis. Although this reduced the spread of ages from some reef units, it did not significantly alter outlying ages, which remained stratigraphically inconsistent and again plotted in separate parts of the sea-level curve (Figure 2). This failure to address fundamental stratigraphic consistency of these age data and to continue making erroneous age-dependant uplift corrections on every dated coral seriously compromises the Glacial sea-level reconstruction of Thompson and Goldstein (2005) and means that the sea-level peaks are merely dating artifacts.

### Glacial Termination II (MIS-6)

Reports of meltwater pulses during the penultimate deglaciation (MIS-6) have also recently been made. On the Huon Peninsula, Esat et al., (1999) reported that a cave exposing the base of the last interglacial terrace (VII) some 90 m below its crest, contained in-situ corals with 1-cm-thick annual bands, implying growth in a shallow-water reef. These corals returned seven isotopically acceptable  $^{230}\text{Th}$  ages of between 125.6 ka and 133.7 ka (i.e., a 7.2 ka true-age variation) which were averaged to give an age of  $130 \pm 2$  ka (a process which excluded a reliable age of 115 ka). This was compared with a  $134 \pm 2$  ka age average from four corals recovered from 5 to 12 m below the reef-crest reported earlier by Stein et al., (1993), but four significantly younger ages at 2 and 16 m were ignored. By comparing average ages and elevations of these two coral groups, Esat et al., (1999) claimed that sea-level fell rapidly at least 70 m from the level of the 134 ka crest group, and then rose rapidly at least 85 m from that of the 130 ka cave group, with both the fall and the rise occurring within the 4 ka difference between the age groups. Unfortunately, the comparison between these two groups is questionable given that it ignores younger ages from both the down-slope cave site and the up-slope barrier site reported earlier by Stein et al., (1993). It is much more likely that the stratigraphic age inversions at both sites reflect true-age variability (Scholz and Mangini, 2007) and that neither may be accurate (Blanchon, this volume). In the absence of reliable ages, the stratigraphy dictates that the cave is simply the oldest part of terrace VII which accreted vertically as sea-level rose. As a result, claims of a rapid 70 m fall and an equally rapid 85 m rise at the Huon Peninsula during the penultimate deglaciation are extreme and poorly supported by the data.

Similar claims of extreme sea-level variability have also been made from IODP-310 cores recovered from the fore-reef slopes of Tahiti (Thomas et al., 2009). In these cores, two corals recovered from 115 to 118 m below present sea level returned reliable  $^{230}\text{Th}$  ages of 133 and 137 ka respectively. Both corals are typical of shallow-water reef environments but are separated by a 30 cm section of much deeper-reef framework. This led Thomas et al., (2009) to claim that a rapid deepening event drowned the older coral and produced a limited deep reef before sea-level fell rapidly leading to a resumption of shallow reef development. In other words, the return to shallow reefal environments represented a reversal in the rapidly rising sea level during the penultimate deglaciation. Unfortunately, such an interpretation ignores the more plausible possibility that the shallow-water corals were in fact clasts transported down-slope into deeper water. Examination of the cores in their Figures S2 and 3 supports this shallow-clast interpretation, with the deeper coral at 118 m consisting of a 5 cm diameter coral clast enclosed by other basalt- and coral-clasts (which were even identified as clasts in the log description). The other coral, which sits directly on top of the deeper framework, could also be a clast given its small size (20 cm); the fact that it contains surfaces encrusted by coralline algae, upward growth, and apparently horizontal cavity fills could merely be coincidental, indicating it fortuitously landed with an upright orientation. However, a clast interpretation is supported by the lack of coral microbialites which are typical of deglacial reef-framework of Tahiti (Heindel, 2008). Regardless of the interpretation chosen, such extraordinary claims of extreme sea-level changes are clearly not supported by adequate data. As such, the existence of meltwater pulses during the penultimate deglaciation, although likely, remains to be proven by credible reef data.

### Last Interglacial (MIS-5e)

A better supported claim of a more modest meltwater pulse has recently been made from reef development on the Yucatan Peninsula during the last Interglacial (MIS-5e). There, Blanchon et al., (2009) identified an episode of reef-crest demise at +3 m and back-stepping to +6 m. In some parts of the reef, this back-stepping was accompanied by erosion, but in others the sequence between the two reefs was continuous, implying that they grew consecutively on an ecological timescale with no intervening hiatus (Figure 4). In turn, this consecutive development requires that reef-crest back-stepping occurred on an ecological timescale, implying that it was caused by a 2–3 m sea-level jump (Blanchon, 2010). Although the dating precision precluded testing the rise rate, a test of the stratigraphic relations was made by dating samples from both reef-crests. Unfortunately, only the +6 m crest returned strictly reliable  $^{230}\text{Th}$  ages which fell between 119.5 ka and 117 ka. However, these ages were younger than well-dated +3 m reefs that had developed in other areas,

both supporting the stratigraphy and constraining the sea-level rise to around 121 ka. To confirm these results however requires replicating the back-stepping reef stratigraphy and obtaining a reliable chronology in other stable areas.

### Origin of meltwater pulses

The preceding review of individual claims of meltwater pulses shows that solid geological evidence exists only for the 3 jumps in sea level during the last deglaciation at 14.6, 11.4 and 8 ka. Preliminary evidence also exists for a jump at the end of the last Interglaciation around 121 ka, although this requires support from other stable areas. Tabulation of these data shows that the average rise-rate during these jumps was as much as 63 mm/yr (Table 1). In other words, the jumps represent a rise-rate that is as much as 6 times the background deglacial rise-rate and therefore clearly implicate major rapid ice-loss events resulting from ice-sheet collapse (Blanchon and Shaw, 1995).

Linking the timing of sea-level jumps with climatic evidence of ice-sheet instability, however, is hindered by age biases in both marine-radiocarbon and ice-core chronologies (Skinner, 2008; Druffel et al., 2008). Despite such biases, recent improvements in synchronizing ice-core chronologies indicate that meltwater pulses coincide with or closely follow abrupt climatic warming, which was itself preceded by severe cooling episodes, known as Heinrich events, caused when the Laurentide Ice Sheet extended out to the edge of the continental shelf (see Hemming, 2004). For example, the start of Mwp-1a on the Sunda Shelf and Tahiti at 14.6 ka coincides with or closely follows the abrupt onset of Bolling/Allerod warming in the NorthGRIP ice core at 14.7 ka (Steffensen et al., 2008), which is itself preceded by Heinrich event 1 from 14.5 to 17.5 ka (Skinner, 2008). Similarly, Mwp-1b on Barbados, which starts at 11.4 ka, closely follows the abrupt onset of PreBoreal warming in NorthGRIP at 11.7 ka. However, further dating of the base of the

reef-crest sequence in RGF-8 might push the onset of Mwp-1b closer to the ice-core timing (Figure 1). Finally, the timing of Caribbean reef demise at ~8 ka closely follows the onset of warming after the 8.2 ka cold event seen in Greenland ice-cores, and the rapid disintegration of the Laurentide Ice-sheet between 8.2 ka and 8.5 ka (Barber et al., 1999; Carlson et al., 2008). If this phasing between rapid sea-level rise events and abrupt climate warming is confirmed, it will have serious implications for the future stability of remaining ice-sheets under the ongoing episode of anthropogenic global warming.

## MICRITE

Ian G. Macintyre  
Smithsonian Institution, Washington, DC, USA

### Synonyms

[Microcrystalline calcite](#)

### Definition

Micrite is a textural term for microcrystalline carbonates less than 4  $\mu\text{m}$  in size.

### Introduction

The term “micrite” is a contraction of the words “microcrystalline calcite” and was introduced by Folk (1959, p. 8) as an aid in the classification of limestones. Initially, Folk applied the term to microcrystalline calcite ooze in the size range of 1–4  $\mu\text{m}$ . Adding a prefix, he coined terms such as “biomicrite” to refer to fossils in a microcrystalline matrix. In 1974, Folk expanded the meaning of the term “micrite” to encompass all carbonate minerals measuring 1–4  $\mu\text{m}$ . He also added a new term “minimicrite” for sizes less than 1  $\mu\text{m}$ .

Bathurst (1966) applied Folk’s terminology to refer to the process of grain surface alteration to micrite caused by microborings filled with micrite precipitates as “micritization”. However, Friedman (1985) thought that Bathurst and others who used his terminology (e.g., Lloyd, 1971; Gunatilska, 1976; Kobluk and Risk, 1977) were misusing Folk’s terminology that simply referred to a microcrystalline ooze matrix.

It was Alexandersson (1972) who suggested that “micrite” should be a textural term to cover all microcrystalline carbonates. Most subsequent studies of grain alteration or submarine lithification use both “micrite” and “minimicrite” as textural terms (e.g., Land and Moore, 1980; Macintyre and Marshall, 1988; Reid et al., 1992; Reid and Macintyre, 1998; Macintyre and Reid, 1995, 1998).

### Conclusion

In carbonate petrographic studies, the terms micrite (4–1  $\mu\text{m}$ ) and minimicrite (<1  $\mu\text{m}$ ) should be used as textural terms to refer to all microcrystalline carbonates.

## MICROATOLL

Scott Smithers  
James Cook University, Townsville, QLD, Australia

### Definition

Microatolls are intertidal coral colonies with dead, relatively flat, upper surfaces surrounded by an annular rim of living coral (Figure 1a,b). They form when upward coral growth is constrained by prolonged exposure near to shallow water, but polyps on the colony sides remain alive and continue to grow laterally (Scoffin and Stoddart, 1978; Stoddart and Scoffin, 1979; Woodroffe and McLean, 1990). Fossil microatolls are microatolls in which no living polyps survive but the colony morphology is preserved (Figure 1c).

**Microatoll, Figure 1** (a) Living *Porites lutea* microatoll with multiple ringed morphology, reef flat, Cocos Keeling Islands, eastern Indian Ocean; (b) *Heliopora coerulea* microatoll, reef flat Mendhoo, Maldives; (c) Fossil microatolls 4000–5000 years old, Magnetic Island, GBR, Australia; (d) Heliotropic *Goniastrea retiformis* microatolls, Paluma Shoals, GBR, Australia.

## Introduction

Darwin (1842) first described coral microatolls, with further accounts by various other early reef scientists (e.g., Dana, 1872; Semper, 1880). Guppy's (1889) description of “miniature atolls” from the Cocos (Keeling) Islands first compared the living coral annulus on microatolls to the circular reef rim of coral atolls, followed by Agassiz (1895) and Krempf (1927) who referred to microatolls as “diminutive atolls” and “dwarf atolls” respectively. The specific term microatoll was coined by Wood-Jones (1910) who argued that microatolls resemble coral atolls and form because sedimentation restricts coral growth to their peripheral rim, as he proposed in his largely discounted theory of atoll formation. Abe (1937) referred to microatolls as “table-forming corals”, emphasizing their flat dead tops.

Patch reefs composed of multiple coral colonies with raised rims and sand-filled centres have been referred to as microatolls (e.g., Kornicker and Boyd, 1962; Larkum and Steven, 1994), but are better described as “mini-atolls” (Scheer, 1971). Thirty years ago, Scoffin and Stoddart reviewed “the nature and significance of microatolls” and recommended that only single coral colonies be described as microatolls (Scoffin and Stoddart, 1978; Stoddart and Scoffin, 1979). This has been applied with only rare exceptions. The focus of these earlier investigations was almost entirely on microatolls as high quality sea-level indicators

(see Chapter *Sea-Level Indicators*), an application improved further by recent technological advances that have increased the resolution of elevation survey and radiometric dating. Further, exceptional palaeoenvironmental records preserved in the geochemistry and structure of microatoll skeletons are being discovered, and represent exciting new areas for research.

## Microatoll description

Most microatolls develop from massive corals; however, branching and foliaceous corals may also adopt this morphology. *Porites* microatolls are particularly common, and intertidal *Goniastrea* and *Platygyra* colonies also form microatolls on many reefs (Figure 1d). They are most abundant on Indo-Pacific reefs but also occur in the Caribbean. In the most detailed survey to date, 43 species from 23 genera were identified as forming microatolls in the northern Great Barrier Reef (GBR) (Rosen, 1978). Microatolls are usually less than 0.5 m high (vertical thickness) but they can be long-lived growing to several meters in diameter. Massive *Porites* grow at rates of around 1 cm per year, so microatolls of a meter in diameter are typically around 40–50 years old. A fossil microatoll exceeding 9 m in diameter and dated at  $2195 \pm 80$  years BP at its centre and  $1535 \pm 130$  years BP on its margin occurs on Pagan in the Mariana Islands (Siegrist and Randall, 1989), with a similarly large fossil *Porites*

(9.6 m diameter,  $7009 \pm 41$  cal years BP at centre) reported from the Leizhou Peninsula, in the southernmost part of Guangdong province in southern China (Yu et al., 2009). *Porites compressa* microatolls 7 m in diameter occur in Kaneohe Bay, Hawaii (Roy, 1970), and fossil *Porites* microatolls 6 m in diameter occur at several locations on the GBR (Hopley and Barnes, 1985; Hendy et al., 2003). Large microatolls demonstrate continuity of growth for several centuries, but most microatolls are  $< 2$  m in diameter. This probably reflects the relatively low probability of extended survival in shallow reef environments where corals are most vulnerable to a range of debilitating conditions. Microatolls on the northern GBR surveyed by Scoffin and Stoddart (1978, p.105) averaged 0.5 m in diameter, although other than stating that they “vary in size from a few centimeters to a few meters” no statistical description of the variance was offered.

### Microatoll formation

Corals develop into microatolls when prolonged emergence during low tides kills polyps on a colony’s upper surface and constrains subsequent growth to its sides. Tolerances to emergence vary with species; *Goniastrea* and *Platygyra* typically grow higher than *Porites* when they occur on the same reef flat. Other factors have been argued as drivers of upper surface mortality and microatoll formation, including excessive sedimentation (Wood-Jones, 1910), nutrient dynamics, and hydrodynamic stress (Stoddart and Scoffin, 1979); however, the general symmetry developed by individual microatolls and the accordant morphologies developed by neighboring microatolls are difficult to reconcile with these typically and unevenly distributed stresses. Subaerial emergence is clearly the main environmental parameter driving the formation of microatolls in most shallow reef settings, where the absolute elevation of the upper limit to coral growth is a function of the duration of exposure and the intensity of desiccating conditions, which are strongly influenced by elevation relative to a tidally modulated water level. Where microatolls grow in “open water” habitats freely connected to the open ocean, the confining water level is a tidal datum that can be linked to sea level. However, where the ebbing tide is impeded as it drains off the reef, the confining water level is moated above the open water level (see Chapter *Moating*) and thus the upper limit to coral growth is controlled by the height of the moat sill, and is less precisely tied to sea level (Hopley and Isdale, 1977).

The relationship between the upper limit to coral growth and tidal levels may vary with exposure to factors such as wavelet wetting, diurnal, and seasonal tidal patterns, but on the central GBR, where the mean tidal range is 2–3 m, the tops of microatolls within the same field are usually within  $\pm 10$  cm (Chappell et al., 1983). Smithers and Woodroffe (2000) indicate that even greater uniformity is found where the tidal range is smaller, such as at the microtidal Cocos (Keeling) Islands, although even

there microatoll elevations may vary by as much as 40 cm between different habitats (reef flat, intertidal passage, lagoonal) that experience different hydrodynamic conditions. The tops of *Porites* microatolls in open-water habitats on the GBR are usually close to the mean low water spring (MLWS) tide level, but may extend to the mean high water neap (MHWN) tide level in moated habitats (Scoffin and Stoddart, 1978). In the Cocos (Keeling) Islands the tops of open water microatolls are typically elevated approximately midway between MLWS and MLWN.

The relatively flat top developed by coral microatolls is referred to as the microatoll plane (Scoffin and Stoddart, 1978). This surface is rarely perfectly horizontal as the water level which confines upward coral growth is seldom absolutely constant through time. As water levels and the upper limit to coral growth fluctuate over a microatoll’s lifetime, complex microtopographies composed of concentric ridges and swales can progressively develop across the microatoll plane. Hopley (1982) identified four common microatoll forms:

1. “*Classical*” microatolls are the basic discoidal kind, with a relatively flat microatoll plane formed under relatively stable water level;
2. “*Top hat*” microatolls have an elevated centre and lower outer rims. They form where the upper limit to coral growth is abruptly lowered, for example, where a storm breaches the sill of a pond that holds water over the reef flat at low tide (Hopley and Isdale, 1977);
3. “*Uprgrown*” microatolls have low centres encircled by higher living rims. They form where the confining water level has risen, as might occur if falling tides are moated behind a rubble rampart deposited on a reef flat during a storm, or where the reef is subsiding (possibly driven by compaction, or tectonic subsidence);
4. “*Multiple-ringed*” microatolls with concentric undulations across the microatoll plane form when the upper limit to coral growth has oscillated through time, either episodically or dynamically, as may occur where interannual variations in sea level forced by relatively rapidly changing oceanographic and atmospheric conditions – such as ENSO – are experienced.

The progressive development of different microatoll surface morphologies driven by temporal changes in the water level that limits upward coral growth is shown schematically in Figure 2.

### Microatolls and sea level

Where the confining water level is an open water level, this relationship means that microatolls, or collections of microatolls, can be used to reconstruct sea-level histories that spatially and temporally augment those available from instrumental records (see Chapter *Sea-Level Indicators* for diagrams). Microatoll derived sea-level records are generally of two main types: (a) records of mid-late Holocene sea level constructed by comparing the elevations of radiometrically dated fossil microatolls to the

**Microatoll, Figure 2** Schematic cross-sections through microatolls showing progressive development (rings are annual growth rings with most recent growth at living margins), with water level history below. (a) Hemispherical coral as yet unconstrained by emergence at low tide and not yet adopting the microatoll form; (b) “Classical” microatoll developed under relatively stable water level; (c) hemispherical coral transformed into a microatoll after emergence caused by tectonic uplift; (d) “Upgrown” microatoll developed under rising water level conditions; (e) “Top hat” or terraced microatoll recording falls in constraining water level; and (f) “Multiple-ringed” microatoll formed by confining water level that fluctuates both upwards and downwards (after Hopley 1982; Woodroffe and McLean, 1990).

elevation of living microatolls at the same location with a known relationship to a tidal datum; and/or (b) records of interannual or decadal sea-level change reconstructed from detailed analyses of the surface topography of long-lived microatolls or microatolls with overlapping lifespans. Both assume that the tidal datum that is the confining water level is unchanged and as sea level varies the absolute elevation of this tidal datum fluctuates.

In many locations, fossil microatolls, often 5,000–6,000 years old, can be readily identified and compared directly with nearby living counterparts that can be surveyed to a tidal datum. Where the tidal curve has not significantly changed, the relative elevations of microatoll tops document the heights of former constraining water levels. Radiometric dating of the fossil microatolls at different heights assigns a chronology to these water levels (see Chapter *Uranium Series Dating*). Where it is confirmed that fossil microatolls were not moated, these histories of water-level change are also excellent records of sea-level change. This approach has been applied to establish mid-late Holocene sea-level histories on the Central GBR (Chappell et al., 1983), in Torres Strait (Woodroffe et al., 2000), the Pacific (e.g., Nunn, 2000; Goodwin and Harvey, 2008), and Indian Oceans (e.g., Woodroffe and McLean, 1990; Kench et al., 2009).

Microtopographic undulations over the upper surfaces of well-preserved microatolls track interannual variations in the elevation of the confining water level (Woodroffe and McLean, 1990; Smithers and Woodroffe, 2001). The internal skeletal structure of massive microatolls contain annual density bands (see Chapter *Sclerochronology*) that can be used to age the upper limit to coral growth over the microatoll’s lifetime (preserved as the topography of the microatoll plane), usually by counting back the density bands from the living edge at the time of sampling. Rapid rises that exceed maximum coral growth rates will not be fully recorded, but microatoll microtopographies may yield detailed sea-level records extending back decades and centuries in modern corals (Woodroffe and McLean, 1990; Smithers and Woodroffe, 2001; Spencer et al., 1997), and also in well-preserved fossil microatolls of mid-Holocene age (Yu et al., 2009).

### Microatoll records of ENSOs, earthquakes, and other environmental conditions

Microatolls are also excellent archives of a range of other environmental conditions. These include the following:

- (a) El-Nino Southern Oscillation (ENSO) events: Sea-level changes accompany shifts from El Nino to La

Nina conditions and associated ENSO cycles, and it has been demonstrated that microatolls in the Pacific Ocean preserve smoothed records of these oscillations across their upper surfaces (Woodroffe and McLean, 1990; Spencer et al., 1997; Woodroffe and Gagan, 2000). The records are smoothed because the record is biologically mediated and only rises in sea level below the coral growth rate ( $\sim 1\text{--}2$  cm a year for massive *Porites*) can be completely recorded. Furthermore, in mid-ocean settings changes in sea surface temperature (SST) and salinity (SSS) related to ENSO are documented by the geochemistry of microatoll skeletons (see Chapter *Palaeoclimate from Corals*), with high fidelity between adjacent corals (Woodroffe and Gagan, 2000). Concerns that geochemical records from microatolls may not represent oceanic water conditions appear allayed by studies that demonstrate excellent correlations between these geochemical records and instrumental SST datasets. Narrow stress bands may also be deposited in microatoll skeletons when conditions for coral growth become critical – and these may document the occurrence of past severe ENSO or other stress events.

- (b) Tectonic movements and event prediction: Microatolls respond to relative sea level and thus their surface morphologies reflect not only fluctuations in the sea surface but also movements of the substrates on which they grow (see Figure 2c). Microatolls in tectonically active areas have been used to establish histories of subduction or uplift associated with earthquakes or more subtle interseismic crustal deformation processes (Taylor et al., 1987; Zachariasen et al., 2000; Natawidjaja et al., 2004, 2006, 2007; Briggs et al., 2006), to investigate spatial patterns of plate rupture during single and multiple events (Konca et al., 2008), and to calculate the rates of tectonic stress accumulation, the frequency of past tectonic events, and the probability of future tectonic hazards (Sieh, 2006; Sieh et al., 2008). For example, Briggs et al. (2006) used GPS measurements of coral microatolls to establish abrupt coseismic uplift of reefs at Nias by as much as 3 m during the Great 2005 Nias-Simeulue earthquake, which followed decades of strain accumulation and submergence, documented by the development of “upgrown” microatolls.
- (c) Other environmental parameters: Coral microatolls confirm that a reef has reached sea level and are critical evidence in geomorphological investigations of reef structure and growth. For example, fossil microatolls across reef flats can reveal reef flat progradation histories (Smithers et al., 2006). Storm histories can also be derived from microatolls, either from upper surface patterns of moated microatolls where moat height or integrity (and thus moated water level) is affected by storms (Hopley and Isdale, 1977) or where storms cause tilting of the microatoll plane (relative to the pre-storm alignment), the timing of which can be derived from the colony’s internal structure. Some

microatolls grow in areas where tidal conditions only expose the coral during daylight at a particular time of year. For example, on the Central GBR daytime low spring tides only occur during the winter months, when the sun is in the northern sky. As a result, higher growing microatolls, such as those formed by *Goniastrea* and *Platygyra*, develop tilted tops in which the northern, more directly radiated section of the living rim is lower than the “lee” side (Figure 1d). Buskirk et al., (1981) reported similar microatolls with tops dipping towards the sun from Vanuatu. This pattern is usually developed across entire microatoll fields, and where storms have affected these reefs, disturbance of this pattern is conspicuous.

## Summary

Coral microatolls are excellent sea-level indicators. Advances in survey and radiometric dating technologies that have improved both elevational and temporal resolution have further enhanced their utility. Furthermore, in recent decades researchers have discovered that microatolls yield excellent data on a broader range of environmental phenomena including atmospheric, oceanic, and tectonic processes. These high-resolution datasets augment more recent and scattered instrumental records both spatially and temporally, improving knowledge of the natural variability and significance of recent changes in these parameters.

## MICROBES

Elizabeth A. Dinsdale  
San Diego State University, San Diego, CA, USA

### Definition

Microbes are microscopic organisms. Many organisms fit into this size category, including, Bacteria, Archaea, Fungi, Protists, etc. The definition provided here uses microbes to describe Bacteria and Archaea. These two groups are unicellular organisms, which do not contain a nucleus and rarely harbor membrane-bound organelles. Both Bacteria and Archaea were classified together as Prokaryotes, but this classification is no longer considered appropriate, because these two groups evolved from separate lineages.

### Microbial association with corals: holobiont

Corals exist as a community of multiple organisms that work together, termed the coral holobiont (Knowlton and Rohwer, 2003). These organisms include the coral animal, microbes, Fungi, endolithic algae, and zooxanthellae (Rohwer et al., 2002; Wegley et al., 2004). Microbes associated with corals are diverse, numerous and provide many functions (Kushmaro et al., 1996; Frias-Lopez et al., 2002). Microbes form species-specific associations (Rohwer et al., 2001); however, some taxonomic variation occurs between reefs (Littman et al., 2009).

### Functional role of microbes

Metagenomic analysis shows that microbes possess a gene complement that allows them to perform a diverse variety of functions (Wegley et al., 2007). Coral associated microbes have the genes to breakdown complex sugars and proteins, reflecting the types of carbohydrates excreted by the coral animal. Nitrogen fixation, ammonia assimilation, and nitrate/nitrite ammonification are functions that the coral associated microbes can conduct and these would enhance nitrogen recycling within the holobiont and potentially supplement supplies of nitrogen to the zooxanthellae. Coral associated microbes possessed multiple pathways involved in sulfur cycling. Microbes associated with Dimethylsulfoniopropionate (DMSP) breakdown are also common within the coral holobiont (Raina et al., 2009). Since sulfur is an essential element in the biosynthesis of amino acids, the microbial community may be playing a pivotal role in the coral growth. Other mutualistic benefits provided by the microbes include, the release of secondary metabolites, such as antibiotics (Castillo et al., 2001).

### Microbial role in coral stress

Changes in microbial complement associated with changes in environmental conditions may exacerbate coral stress. Corals exposed to four stressors, including increased organic carbon, inorganic nutrients, temperature, and

reduced pH, showed a variation in their associated microbial assemblage. Genes including those associated with virulence, stress response, sulfur and nitrogen metabolism, motility, and chemotaxis increased within the microbial community of stressed corals. The microbial taxonomic component associated with the stressed coral was dominated by species often associated with disease, including many *Bacteroidetes* and *Fusobacteria* (Vega Thurber et al., 2009).

### Microbial role in altering environmental conditions

Apart from symbiotic microbes, corals are influenced by the microbes present in their surroundings, such as those in the water column or in the substratum. Microbialization of the water column was a feature of coral reefs influenced by high levels of human activity (Dinsdale et al., 2008). On a coral reef with little to no fishing or human habitation microbial numbers were low and their gene complement matched that of a balanced autotrophic/heterotrophic community (Dinsdale et al., 2008). On reefs with higher levels of fishing and human population, microbes were highly abundant and dominated by heterotrophic microbes, many of which were similar to known pathogens. The increase in pathogenic-like microbes was correlated with an increase of unhealthy corals (Dinsdale et al., 2008; Sandin et al., 2008).

## MID HOLOCENE

Sarah Woodroffe  
Durham University Science Laboratories, Durham, UK

### Definition

The Mid Holocene refers to a period of time between c. 7–5 ka cal BP during which large-scale ice sheet melt ceased. In regions far from former ice sheets, it was the first time in the present interglacial that relative sea level (RSL) reached or passed present levels. The end of ice sheet melt caused a change from rapidly rising RSL during the early Holocene (c. 10–7 ka cal BP) to relatively stable RSL between the mid Holocene and present.

### Introduction

The tropical reef environments of the Indo-Pacific and Atlantic have developed in different ways during the Holocene. This is due to the different broad-scale relative sea level (RSL) histories experienced by these two regions through time, particularly during and since the mid Holocene. It is important to understand how global sea level has fluctuated during this period in order to understand how these differences have come about.

The early Holocene period was characterized by a warming climate, which resulted in the complete melt of the Laurentide and Fennoscandinavian ice sheets, and a reduction in the size of the Greenland and Antarctic ice sheets. This large-scale ice sheet melt caused global sea level to rise quickly in far-field, low-latitude locations, which are distant from these ice sheets and are not affected by glacio-isostatic rebound. The rates of RSL rise in some far-field locations exceeded 8 mm/yr during the early Holocene (Sloss et al., 2007). By the mid Holocene, the majority of this melt had ceased; all North American and European ice sheets had disappeared, Antarctica was relatively stable, and the Greenland ice sheet had retreated inside its present margin.

Relative sea level in near and intermediate field locations record the effects of glacio-isostasy (see Chapter entries “*Glacio-Hydro Isostasy*” and “*Postglacial Transgression*”). However, these effects can extend to considerable distances, penetrating well into the tropical waters of the equatorial low latitudes. This is especially so for sites in the Atlantic Ocean which lie within the zone of influence of the former Laurentide Ice Sheet. It is therefore important not to assume that all tropical locations with fringing and barrier reefs lie in far-field locations and are unaffected by glacio-isostasy; tropical reefs in the Caribbean, for example, are not in the far-field zone, whereas the Indo-Pacific region is a genuinely far-field location.

### Equatorial ocean siphoning and continental levering

Results of a study combining glacio-isostatic modeling and RSL observations show that the Caribbean is located sufficiently close to the former Laurentide ice sheet to be on its lithospheric forebulge (Milne et al., 2005). The Laurentide ice sheet depressed the crust over North America and this caused displacement of the lithosphere away from the center of load. This caused a rim of crustal uplift outside of the depressed zone. When the ice sheet melted, the lithosphere migrated back to the former center of load and caused the forebulge to collapse. During the early Holocene, the effects of this process were masked by rapidly rising sea level caused by ice sheet melt, but since the mid Holocene this process can be seen in RSL records from both the forebulge region itself, and further away in the far-field.

In tectonically stable locations in the Caribbean, RSL has risen throughout the mid-late Holocene, despite the end of global ice melt c. 7–5 ka cal BP, because of direct crustal subsidence caused by forebulge collapse. In contrast, in the Indo-Pacific region RSL has fallen by a small amount (c. 1–2 m) in the late Holocene, as water has moved from the far-field regions back into space created by crustal subsidence in the forebulge region. This process is known as equatorial ocean siphoning (Mitrovica and Peltier, 1991).

A second process that may be as important as equatorial ocean siphoning in explaining late Holocene RSL fall in the Indo-Pacific region is continental levering. As the underwater shelves around continents were progressively flooded under rising sea level during the early Holocene, they subsided under the increased weight of water on them. Water from the center of large ocean basins (e.g. Indian and Pacific Oceans) flooded into the space created by these subsiding shelves, causing RSL to fall in the center of these ocean basins. Model results suggest that RSL fall in these locations comprises c. 60% due to forebulge collapse and 40% due to offshore subsidence around continental margins (Mitrovica and Milne, 2002).

### Effects on reef development

Reef development differences between the Caribbean (forebulge zone) and the Indo-Pacific (far-field), and within

the Indo-Pacific region itself (central ocean vs. continental margin sites), have been affected by the two processes described above. In the early Holocene, fast rising sea level in both regions provided accommodation space for reef growth, but after the mid Holocene (c. 7–5 ka cal BP) their broad histories diverge (see Chapter entries “*Holocene Reefs : Thickness and Characteristics*”, “*Sea Level Changes and Effects on Reef Growth*”, “*Reef Classification, Response to Sea Level Rise*,” and “*Reef structure*”).

### Caribbean model

Fast rising RSL in the early Holocene allowed high reef accretion rates, particularly in the Caribbean, where the average reef growth rate was c. 6 m/kyr (Dullo, 2005). Caribbean reef-building coral consists primarily of *Acropora cervicornis* (which grows in 5–15 m water depth) and *Acropora palmata* (which grows in <5 m water depth). Therefore, most Caribbean reef growth occurred after RSL rose to within 15 m of present (c. 9 ka cal BP) (Toscano and Macintyre, 2003). The exact timing of reef initiation depends on the depth of the antecedent surface, and can vary by c. 5 ka in locations with different reef-base elevations (Hopley et al., 2007). Caribbean reef-building corals were able to keep pace with RSL rise during the early Holocene (keep-up mode: Neumann and Macintyre, 1985), but as RSL slowed in the mid Holocene, back reef zones developed dominated by unconsolidated sand and rubble, representing a late succession stage of Caribbean reef development (Steneck et al., 1998; Gischler and Hudson, 2004). As RSL continued to rise at a slower rate in the late Holocene, *Acropora palmata* accretion continued to keep pace and slowly developed into framework-coral-covered reef flats.

### Indo-Pacific model

In the Indo-Pacific, RSL rose more rapidly in the early Holocene than in the Caribbean, although initial inundation of the –15 m contour occurred at about the same time (c. 9 ka cal BP: Pirazzoli, 1991). Unlike in the Caribbean, reef-building coral (*Acroporids* and *Poritids*) was unable to keep pace with RSL rise, entering instead a ‘catch-up’ mode where reef accretion lagged RSL rise (McLean and Woodroffe, 1994). As RSL rose to present in the mid Holocene, coral growth caught up with RSL, robust head corals with a dense framework were laid down, and an algal crust developed. The exact timing of reef attaining sea level is dictated by the depth of the antecedent surface and the amount of ‘catch-up’ it had to undergo, although this age range is much less than in the Caribbean because of the abrupt nature of RSL stabilization in the mid Holocene.

Under stable RSL from the mid Holocene onwards, tectonically stable locations saw lateral reef development as accommodation space for vertical reef growth disappeared. In many oceanic locations, this produced large reef flats and detrital carbonate platforms (Hopley, 1985). As RSL began to fall in the center of the Indo-Pacific ocean basins in the mid-late Holocene, these platforms became

emerged at low tide causing any coral living on them to die. There are many examples of coral microatolls from mid to late Holocene time stranded above their growth position on exposed reef flats in the Indo-Pacific region (e.g. Cocos Keeling Islands: Woodroffe, 2005).

These two idealized models of reef development under RSL rise assume no factors other than eustatic sea level affect reef growth. There are, however, some locations in the Indo-Pacific (e.g. Tahiti) where RSL has continued to rise through the Holocene and reef development has followed more closely the Caribbean than Indo-Pacific model. This is due to a variety of factors including volcanic and tectonic subsidence, which have caused continual, gradual submergence of Tahiti as it migrates away from a volcanic hotspot (see Chapter entry “*Volcanic loading and Isostasy*”). Similarly, in the Caribbean there are emerged mid Holocene corals on the island of Barbados, which are evidence of plate tectonic movement in this seismically active zone (Schellmann and Radtke, 2004).

While sea level was an important influence on the growth of coral reefs worldwide during the mid Holocene, other elements of the coral growth environment may also have been different to today’s. The period is often referred to as the Holocene Climatic Optimum and in the tropics much of the climatic data comes from the corals themselves (see Chapter entry “*Palaeoclimate from corals*”).

For many areas such as the Great Barrier Reef (GBR), a warmer climate of about 1.3°C, less variable wet seasons, fewer droughts, floods, and weaker ENSO events produced higher growth rates of individual corals (Gagan et al., 1998) and of coral reefs (see Hopley et al., 2007, ch. 11) within the period 8–7 ka which saw the most rapid reef growth on the GBR. Similar warmer, wetter conditions (from stronger monsoons) have been recorded elsewhere in the tropics in the mid Holocene (e.g. Gagan et al., 2000).

### Case study: the Great Barrier Reef

The GBR provides an example of how different types of reef morphology are dependent on different RSL conditions. The GBR shelf is wide (c. 230 km at its widest point) and has undergone differential movement through the Holocene. The offshore part of the shelf has subsided over time compared to the inner shelf due to hydro-isostatic loading, resulting in continuous RSL rise at the outer edge and a mid-late Holocene RSL fall on the inner part of the shelf (Nakada and Lambeck, 1989; Woodroffe, 2009). The reefs at the outer edge of the shelf are primarily made up of framework coral, most often found in keep-up situations, like those of the Caribbean. Inner shelf reefs, on the other hand, are described as ‘detrital piles with coral caps’ (Hopley et al., 2007, p. 390), with unconsolidated sediment increasing significantly across the shelf. Inner shelf reefs have also undergone emergence and erosion through the mid-late Holocene under slowly falling RSL.

Another factor affecting reef growth and morphology was the “mid *Holocene High Energy Window*” (see entry).

On the GBR, this existed between about 8 and 5.5 ka when outer reefs lagged behind those of the inner shelf (including fringing reefs) and did not protect the inner shelf reefs. Much of the carbonate productivity went into building coral shingle ridges on the shores of adjacent high islands. Subsequently, there has been a decline in both the rate of reef growth (including fringing reef progradation) and shingle ridge accumulation (Smithers et al., 2006).

### Summary/conclusions

Broadly speaking, reef accretion in both the Indo-Pacific and Caribbean regions is dominated by ice-sheet-melt-driven sea-level changes through the Holocene. Differences in reef morphology between the two regions, including the amount of framework coral and the extent of reef flats, reflect relatively small-scale variations in regional RSL, which occurred since the mid Holocene. These differences are due to long-lived global-scale isostatic processes which cause sea-floor subsidence (RSL rise) in some regions and RSL fall in others since the mid Holocene.

### Introduction

Midway Atoll is a subtropical reef near the northwestern end of the Hawaiian Archipelago at 28° 12' N and 177° 22' W, approximately 2,000 km from Honolulu and 259 km east of the International Date Line. Midway is an unincorporated U.S. territory and the only island in the archipelago not a part of the State of Hawai'i. It is second only to neighboring Kure Atoll, 60 km to the northeast, as the Pacific's most northerly atoll. Midway is roughly 9 km in diameter; 40 km<sup>2</sup> in total area; contains two main islands, Sand (1,200 ha) and Eastern (135 ha);

**Midway Atoll (Hawaiian Archipelago), Figure 1** Satellite view of Midway Atoll, showing Eastern and Sand Islands (southeast and south), the dredged channel through the perimeter reef (south), and the lagoon and pinnacle reefs (center). Source: Courtesy of Quickbird satellite imagery, 2007.

and one smaller islet, Spit Island (2 ha), (Figure 1). The atoll includes a large, shallow, triangular perimeter reef that encircles a mostly shallow lagoon (6,000 ha) with a maximum depth of 20 m. The perimeter has emergent reef along its northern sector. A similar emergent reef is also found along the northern rim of Kure Atoll suggesting a common origin.

### Geology

Midway was formed approximately 28 million years ago over the same volcanic hotspot that is now forming Hawai'i Island, the largest and south-easternmost island in the chain, 2,500 km southeast of Midway. Midway and Kure Atolls are at the northwest end of the Hawaiian Islands, and are among the six atolls, one low reef island, three high volcanic islands, and 30 submerged banks comprising the Northwestern Hawaiian Islands (Figure 2). Further to the northwest of Kure and Midway, the chain continues as a series of older drowned atolls and islands, called the Emperor Seamounts that extends to the Bering and Kamchatka Trenches off northern Siberia.

In 1965, the U.S. Geological Survey took vertical core samples at Midway and hit the solid basaltic rock formed by ancient volcanic eruptions at 55 m beneath Sand Island and 378 m beneath the reef at the northern edge of the lagoon (Figure 3). Core analyses of foraminifera and

limestone revealed a very complex evolution of reef and sediment deposits dating back to the Miocene that formed in shallow waters and providing evidence that the coral reefs have maintained upward growth as the atoll's volcanic base subsided. At least two Pleistocene unconformities were noted in upper layers, providing evidence of multiple episodes of sea level rise and fall. The thickness of the atoll's Holocene reef is approximately 160 m, and sediments in the lagoon are 384 m thick consisting of post Miocene deposits. Analysis of fossil corals in the core reveals that previous climatic conditions at Midway were more favorable for growth and abundance of corals. As with contemporary reefs at Midway, coralline algae were also dominant calcifying organisms.

### Human history

The first recorded landing at Midway Atoll was made in 1859 by Captain N.C. Brooks aboard the ship *Gambia*. In 1867, the Secretary of the Navy sent Captain Reynolds to take possession of the atoll for the United States. Efforts in 1871 to establish a settlement and open a channel through the perimeter reef failed, and for the next 30 years visits to the atoll were limited to shipwrecked survivors and bird hunters. Midway's role as an important communication link was established in 1903 when the Commercial Pacific Cable Company chose Sand Island for one of

**Midway Atoll (Hawaiian Archipelago), Figure 2** Map of the Hawaiian Islands archipelago with Midway near the northwest end and including all of the 37 submerged banks which are numbered. Source: Grigg and Epp (1989).

its relay stations. Cable Company employees reported foreigners landing at Midway, and especially disturbing were Japanese feather hunters who since the 1880s had decimated nesting seabird colonies. In January 1903, President Theodore Roosevelt placed the Midway Islands under the jurisdiction and control of the Navy Department to stop the “wanton destruction of birds that breed on Midway” and to establish a coaling station for Navy warships. In 1935, Pan American World Airways established a seaplane base in the harbor, including the clearing of some coral heads from the lagoon, and constructed a small luxury hotel on Sand Island. Midway became a regular refueling stop on a trans-Pacific route that also included Honolulu, Wake Island, Guam, and Manila. The short-lived era of the “flying clipper” seaplanes ended with the onset of World War II, and in early 1941, a U.S. Naval Air Station was commissioned on Midway. In the summer of 1941, 1,500 workers and a dozen dredges began excavation of the deep ship channel through the southern perimeter reef. “The big lagoon impounded incalculable tons of water coming in over the reefs, and poured it all out through the new channel in a current that often reached six miles per hour”, Woodbury (1946) reported. The dredging lowered lagoon water levels and exposed some of the perimeter back reefs. Likely changes in lagoon circulation included suspension of fine colloidal sediments accumulating on the lagoon floor caused by changes in deep water circulation patterns attributed to the new channel. On December 7, 1941, Japanese war planes bombed both Midway and Pearl Harbor.

Midway is well known for its role in the Battle of Midway. On June 3, 1942, a Japanese occupation fleet was spotted by a Midway patrol plane, and early on June 4, Japanese carriers launched three waves of planes to destroy the air base at Midway and clear the way for

occupation. Airplanes on both sides of the battle were lost, and extensive physical damage and casualties occurred on Sand and Eastern islands. From June 4–6, most of the battle was fought in open seas northwest of Midway. The Japanese Navy never fully recovered from the loss of all four of its carriers, 256 aircraft, and more than 400 of its best aircrew, and the battle terminated Japanese eastward expansion in the Pacific. The WWII facilities at Sand and Eastern Islands were listed on the National Register of Historic Places on May 28, 1987.

Midway continued to serve as a strategic location for the military after the war. During the Korean conflict, Midway served as a refueling station, and in the late 1950s “Cold War”, Midway was substantially upgraded and became a central location for the Distant Early Warning Line’s Pacific Barrier, extending from Midway to Adak, Alaska. During the Vietnam War, Midway was a main aircraft and ship refueling station and served as a listening post for foreign submarine activity. Midway was the site of the June 1969 meeting of President Thieu of the Republic of Vietnam and President Richard Nixon. In the waning years of the Cold War, Midway’s strategic importance as a military base diminished, but its unique historic associations and superb wildlife habitat quickly gained recognition.

An overlay refuge at Midway Atoll was established in 1988 when the U.S. Navy invited the U.S. Fish and Wildlife Service (FWS) to manage the atoll’s extensive wildlife resources. In 1992, the Department of Defense announced plans to close the Midway Naval Air Facility, and in 1996, the FWS assumed expanded jurisdiction over Midway after President Bill Clinton signed an Executive Order that transferred the atoll to the Service. Despite the efforts of Navy to clean up the atoll before transfer to the FWS, there are residual contaminated areas on the main islands where

**Midway Atoll (Hawaiian Archipelago), Figure 3** Preliminary logs of two 1965 Midway Atoll drill holes showing lithography, core recovery, and carbonate mineral composition of the cores. Source: Ladd et al. (1967).

soldiers defended the atoll during WWII, and where up to several thousand dependents, contractors, and soldiers lived and worked for more than half a century. Also, metallic debris remains in near shore waters as well as evidence of seeping contaminants and petroleum residues from the main islands.

The National Wildlife Refuge boundaries encompass “1,472 acres” of emergent land and “580,392 acres” of submerged lands and waters, out to “12 nautical miles”

(nmi). On June 15, 2006, President Bush added the Midway NWR in his Proclamation designating the NWHI Marine National Monument (MNM), and in 2007, its name was changed to the Papahānaumokuākea MNM. The Monument is managed by the NOAA, FWS, and the State of Hawai‘i, and it protects all 10 of the NWHI out to a distance of 50 nmi, including 30 submerged reefs inside the MNM boundaries. Midway is presently the only destination in the Monument open to public visitation.

## Marine species and habitats

Midway Atoll location in subtropical waters offers unique opportunities to study the effect of colder waters on the growth, development, and ecology of coral reefs. The atoll drops off steeply outside the perimeter reef, making it possible to observe within a relatively small area the different organisms and communities associated with pelagic, reef crest, ocean reef slope, deep reef, and lagoon habitats. The lagoon contains circular patch reefs in the deep central lagoon (Figure 1) and shallow back reefs near the lagoon perimeter. Both impede water circulation and trap sand washed over the reefs. These sediments limit coral development in much of the lagoon, except in the deeper central lagoon where stands of the endemic finger coral (*Porites compressa*) flourish. Corals are more abundant on some leeward ocean facing reefs and shallow back-reefs and lagoon pinnacles, but overall, corals are scarce on reefs exposed to ocean waves. A total of 33 species of stony corals and two non-stony corals (*Palythoa* and *Sinularia*) have been recorded at Midway, based on surveys from 2000–2006 and are dominated by *Pocillopora*, *Porites*, and *Montipora* species. These totals are slightly less than the 34–46 species found at the four nearest NWHI atolls and much less than the 66 species at the furthest atoll, French Frigate Shoals (FFS), 1,300 km to the southeast within the MNM. The close proximity of FFS to Johnston Atoll may facilitate dispersal of coral species between the Hawaiian and Line archipelagos and help explain the much higher species totals at FFS. The dominant blue encrusting coral at Midway is now tentatively identified as *Montipora dilatata*, an endemic species that displays spectacular formations in the lagoon and back reef habitats at Midway and several neighboring atolls, but which is rare in the larger MHI. Approximately 12 of the Midway coral species are endemic (~40%), an above-average level for the NWHI but comparable to the remaining NWHI.

In September 2002, marine biologists were surprised to find extensive bleaching of corals at Midway and two neighboring atolls (Kure and Pearl and Hermes) in these subtropical waters. Less severe bleaching occurred again at the same atolls during the late summer of 2004. Corals at Midway, where the 2002 bleaching was especially severe, must adapt to colder winter water temperatures of 18°C, as well as adapting to summer temperatures, normally 8–10 degrees higher. During the bleaching event of 2002, temperatures reached 29°C, 11° higher than the winter lows, and the corals responded by bleaching. Corals have recovered well during the past several years although there has been a net loss of lobe coral (*Porites*) compared to levels at permanent transects in the lagoon prior to the bleaching events at Midway.

Patches of the seagrass (*Halophila*) are reported in the lagoon, and calcareous green algae, brown turban algae, and crustose coralline algae are common on the outer reef crests. Large numbers of rock boring sea urchins (*Echinometra*, *Heterocentrotus*, and *Echinostrephus*) predominate, hollowing out the dead skeletal portions of live

lobe corals (*Porites*) and riddling the coralline algal covered reef crest with numerous holes and burrows. Scientists of the University of California at Santa Cruz are now determining whether reef erosion primarily from the boring urchins is outstripping reef growth, and whether selective removal of urchins would prevent serious erosion of the perimeter reef crests, the main natural barrier protecting the lagoon and islands. Beyond the reef massive spurs and grooves high in coralline algal cover face the open ocean along the northwest to southwest perimeter reefs, providing clear evidence of the importance of coralline algae as a major reef builder and bulwark in the far end of the NWHI. More than 100 species of algae are now known from Midway, including 35 new records for Midway and one species new to science, *Dudresnaya babbittiana*. A thorough 1997 survey reported no alien algal species at Midway. Quantitative surveys in 2006 revealed that *Lobophora*, *Laurencia*, *Microdictyon*, *Padina*, crustose coralline algae, and *Halimeda* in descending order were the most abundant algae at Midway.

The first systematic marine invertebrate survey was done at Midway in 1997. It documented 316 invertebrate species, 250 of which had not been previously recorded at Midway. Crustaceans dominated the larger invertebrate species, composing 46% of the total species. Other conspicuous marine invertebrates included sea urchins, with the burrowing sea urchin *Echinostrephus* responsible for the highest densities in the NWHI reported at Midway and Kure (>12 individuals/m<sup>2</sup>). The most common sea cucumber was *Actinopyga* and the most common sea star was *Linckia multifora*. The crown-of-thorns sea star, *Acanthaster planci*, has been reported at Midway at low levels. The black-lipped pearl oyster, *Pinctada margaritifera*, has also been recently reported at Midway.

A total of 258 species of fish, including 7 pelagic species, have been recorded on Midway reefs by 1993. Despite its low species diversity, Midway's reef fish biomass is higher than in the MHI, largely due to reduced fishing pressures attributed to the protective mandate of the NWR. Midway ranked fifth in terms of species richness, but ranked first in numerical density (2.7 individuals/m<sup>2</sup>), and ranked second in fish biomass, (2.5 t/ha) among all locations in the NWHI. Many Midway species grow to larger than average size, and all trophic levels are well represented, including jacks and four species of sharks. Some of these species are either not found on shallow reef habitats in the MHI or are very rare there. Several of these are limited to deep waters in the MHI, but are found at shallow diving depths (15–50 m) at Midway, including the only endemic Hawaiian grouper, the hapu'upu'u, (*Epinephelus quernus*) a species commercially harvested at greater depths (150–200 m) in the MHI, but fully protected within Midway NWR. This disparity in depth distribution is explained by the fish staying in the same isotherms extending upward to shallower depths at Midway compared to their greater depth regimes in the MHI.

Threatened green sea turtles are frequently seen inside the lagoon and basking on beaches, and 2007–2008 marked the first turtle nesting in many years. Endangered hawksbill sea turtles (*Eretmochelys imbricata*) are infrequently seen in the lagoon. About 65 endangered Hawaiian monk seals (*Monachus shauinlandsi*) are usually present at Midway at any time, and pup levels have increased significantly since the establishment of the NWR in 1996. Approximately 150–200 Hawaiian spinner dolphins use Midway's lagoon; bottlenose dolphins are commonly seen outside the reef; and striped dolphins, spotted dolphins, and rough-toothed dolphins have also been reported. Endangered humpback whales and other whales are also occasionally seen off Midway.

### Terrestrial wildlife and habitats

Humans have greatly changed Midway Atoll from its original form. The combined effects of dredging and filling, seawall construction, and importation of herbs and many plant species has greatly expanded the original acreage and made Midway a different place, but one that is still a wildlife habitat of worldwide importance. The earliest botanical descriptions of Midway were made in 1902, and since then more than 265 different terrestrial taxa have been identified. Nine of these are endemic to the NWHI and another 17 are indigenous to the HI. One endemic plant species, *Cenchrus agriminoides* var. *laysanensis*, is listed as endangered. Ecological restoration efforts are underway to eradicate invasive and noxious weeds, control others, and restore some habitats with native species. Since the first insect (a moth) was described from Midway in 1894, more than 300 species of arthropods and land snails have been found on Midway, mostly introduced aliens.

Almost two million breeding seabirds of 15 species make Midway one of the most important breeding areas of seabird conservation in the Pacific. Midway hosts the world's largest populations of both the Laysan albatross (396,936 nesting pairs) and black-footed albatross (23,963 nesting pairs) in 2009, accounting for 67 and 39% of the world's totals, respectively. One or two endangered short-tailed albatross generally visit Midway each year, but none have nested yet. Midway's breeding populations of white terns, black noddies, and red-tailed tropicbirds constitute the largest colonies in the Hawaiian archipelago. After eradication of rats in the mid-1990s, the Bonin petrel colony at Midway had rebounded to more than 32,000 pairs by 2005.

In 2004, 20 endangered Laysan Ducks, were transported to Midway from their only home at the time, Laysan Island, within the Hawaiian Islands National Wildlife Refuge (now also within the Papahānaumokuākea MNM). Biologists wanted to establish a second "insurance" population of this endemic duck once found throughout the Hawaiian Islands whose distribution had declined during the past two centuries to the single hyper-saline lake at Laysan Island. The ducks have adapted well to Sand Island, surprising biologists by breeding during their first year on Midway, with at least

10 ducklings surviving. An additional 22 ducks were transported to Midway in 2005, most of which were introduced to Eastern Island. Over the last several years there were declines due to disease, but duck populations have now rebounded to their highest levels at Midway. The atoll also serves as an over-wintering area for several arctic migrant shorebirds, including the globally rare Bristle-thighed curlew. Predator-free islands are required for this large but vulnerable shorebird because they become flightless during their winter molt. Many other migratory birds also visit Midway, some regularly and some rarely.

### Current investigations

The provisions of the MNM include the total ban of commercial fishing by 2011, control of access and introduction of alien species, and monitoring, safeguarding, and restoring the many endemic, threatened and endangered species that depend upon Midway and the other atolls and reefs within the MNM for their survival. A management plan for the Monument has been coordinated and approved, and a research plan will soon be completed.

Some research will be devoted to tracking and promoting recovery of depleted, endangered or threatened species as well as fish targeted by commercial fishers that will become fully protected in 2011. Because general visitation will be allowed only at Midway within the Monument, there will be considerable monitoring and controlling of visitors to prevent harm to fish and wildlife, collecting of fish and wildlife, preventing the introduction of invasive and alien species, and minimizing the effects of trash and pollution. Much of the Monument marine habitats including offshore habitats at Midway still remain relatively unexplored, and so some effort will be devoted to exploration for new species and habitats to determine which need to be afforded special status and additional protection. Research will also be conducted to learn more about how relatively pristine reefs function and what lessons can be learned from comparisons with the status of stressed reefs outside the Monument. In addition, research efforts will continue to determine whether reef growth at Midway is keeping pace with erosion and subsidence, and whether additional measures will help to reduce adverse effects, such as selective removal of the large populations of sea urchins that are now eroding key shallow reefs that serve as natural breakwaters for protecting the entire atoll.

Floating marine debris discarded or lost by distant fishing fleets in East Asia continues to accumulate regularly at Midway. Since 1996 when cleanup efforts were initiated, 42,821 kg has been removed from Midway which ranks fifth in total quantity removed. Evidence of increased accumulation rates on the shores and reefs of the NWHI may be attributed to the southward movement of the Subtropical Convergence Zone in the north central Pacific.

### Controversies and gaps in current knowledge

A review of the field methods supporting the Darwin Point hypothesis (Grigg, 1982) revealed it relied primarily on

limited sampling of one coral species, with little attention directed at crustose coralline algae that dominate shallow reefs at Kure, Midway, and neighboring islands and atolls. The hypothesis also relied on annual mean seawater temperatures and ignored seasonal fluctuations, especially at Kure, Midway, and Pearl and Hermes Atolls. Cooler winter temperatures are thought to reduce coral growth rates, but the summer temperatures are similar along the entire NWHI and high enough not to reduce coral growth rates. Moreover, the warmest summer temperatures that resulted in the coral bleaching events of 2002 and 2004 at the northernmost atolls may be caused by reduced mixing from weaker winds situated closer to the center of the North Pacific high pressure ridge and by decreased circulation within large shallow lagoons (Brainard et al., 2004). Regardless, the atolls have fully recovered from the earlier bleaching as documented by coral re-growth and recolonization of earlier bleached habitats.

Siciliano (2005) reexamined the Darwin Point hypothesis and reported that, although coral growth rates generally decline as a function of increasing latitude in the NWHI, as first suggested by Grigg (1982), this decrease is habitat-specific. Coral colonies found in protected habitats throughout the NWHI chain (back reef and lagoon habitats on the atolls; bays sheltered from wave action at the islands lacking lagoons) show comparable growth rates of corals regardless of latitude. This may be explained by the microclimatic conditions experienced by corals growing in the shallower, and often warmer lagoon and back reef habitats, where they are not closely related to offshore SST. Conversely, corals growing in exposed habitats throughout the NWHI (fore reef of atolls and reef islands), experience temperatures more akin to offshore SST conditions, and therefore may be more likely to correlate to regional SST gradients, such as decreasing SST with increasing latitude corresponding to decreasing growth rates.

However, the growth rates measured by Grigg (1982) may also be underestimated at Kure Atoll because of selective sampling. In his assessment of coral growth rate throughout the NWHI, Grigg (1982) sampled *Porites lobata* exclusively at 10 m depths at exposed southwest facing fore reefs. Inspection of *Porites* growth rates in three habitats at Kure Atoll (Table 1, from Siciliano, 2005) reveals that the fore reef has the lowest growth rate for this genus, among all sites sampled. There is strong

evidence of local upwelling off the southwest sides of the islands and atolls of the NWHI resulting in cooler waters. Therefore, exclusive sampling from this area is likely to underestimate average growth rates for the atoll as a whole. Even so, the Siciliano (2005) growth rates of *Porites* from the fore reef habitat (4.5 mm/yr) were still higher than those reported by Grigg for *Porites lobata* (3 mm/yr), even if the data comparisons excluded the faster growing, branching species such as *Porites compressa* which is present but not common on Kure's fore reef. However, additional encrusting and massive growth forms of *P. lobata* and *P. evermanni* were included in the 2005 study because they are important reef builders at Kure. Inspection of Table 4.6 also indicates that, if *Porites* growth rates were adjusted to reflect those of other reef-building corals in the fore reef habitat using Grigg's approach (i.e., by averaging the *Porites* growth rates with those of other reef-building genera), the corals' growth rate would increase to 0.8 mm/yr, rather than decrease as suggested by Grigg (1982) who reported an adjusted growth rate of 0.2 mm/yr for Kure Atoll, the basis for proposing the atoll as the Darwin Point. As a result, the latter data sets do not support the early findings of Grigg (1982).

## Summary and conclusions

Midway Atoll has experienced numerous changes over the past century but is now fully protected indefinitely. Adequate funding for management and restoration measures will contribute to the resilience and survival of the atoll, its habitats, vegetation, fish, and other wildlife. More importantly, Midway is now open again for public visitation that will serve to educate many people about the beauty and value of the Refuge and in turn, promote support and continued protection by future generations.

Factors not necessarily limited to latitude or mean annual SST may be responsible for determining the ultimate fate of Kure and Midway atolls and their coral reefs over geological time. These include anthropogenic impacts, excessive bio-erosion, bleaching events, size of the reef caps, duration of geological time in shallow water, geological instability leading to slumping and collapse of reefs, storms, ocean acidification, sea level rise, weather anomalies, and more rapid rates of subsidence as the atoll moves further away from the Hawaiian Rise into the deeper sea floor. More likely the Darwin Point, including its location, size, and validity will likely be further examined and perhaps revised. Alternatively, the Darwin Point theory may be better characterized as a dynamic concept or axiom rather than a defined point on earth, such as being at Kure or neighboring Midway. A spatially explicit alternative might be to restate it as a zone or gradient of approximately 2,000 km in length stretching from Kure and Midway atolls toward the southeast through the more than 30 drowning banks in the MNM to the islands of Kaua'i, O'ahu and Moloka'i where there are several neighboring submerged coral reefs and banks not presently keeping pace with sea level.

## MINING/QUARRYING OF CORAL REEFS

---

Barbara E. Brown  
 School of Biology University of Newcastle, Newcastle,  
 UK

## Definition

The extraction of coral, either in the fossil or living form, for use generally in the construction trade. This is a widespread activity in the Indian Ocean in particular, which results in extensive damage to the three-dimensional structure of the reef and its inhabitants.

Recovery of damaged reefs may be very limited, particularly when surfaces are reduced to mobile rubble which inhibits successful coral colonization and growth.

### Background

Coral mining has caused extensive degradation of reefs in a number of countries, which include India, Maldives, Sri Lanka, Tanzania, and the Philippines (Brown, 1997a). The use of coral rock as a construction material in many countries in the central Indian Ocean has had a long history, particularly in the building of mosques, temples, and shrines. Early photographs taken by Agassiz in Malé in the Maldives in 1903 show houses constructed of coconut leaves and available timber, but by the mid-late twentieth century construction of houses, boundary walls, groynes, and breakwaters with coral blocks was commonplace (Brown, 1997b). At Mafia Island, in Tanzania two forms of coral were extracted in the early to late twentieth century for both local and commercial construction (Dulvy et al., 1995); these were fossilized limestone and living reef coral. In Sri Lanka, corals are primarily used in the construction industry for production of mortar and plaster with subsidiary uses as lime in soil improvement and in the ceramic and cement industry. In India, corals (coral fragments or 'challi' rather than coral 'stones') are also used for the production of lime with lime kilns in the Tuticorin area of southern India, exporting lime all over the country to meet the demands of paper and sugar industries, leather tanning and bleaching, mortar production, and white wash paint. Coral 'stones' extracted from areas such as the Gulf of Mannar, India, are used as building blocks or in road construction and as source material for house decorations. Similarly, in West Sumatra branching and massive corals are extracted to sell as decorative materials for house walls. In the offshore islands, it is estimated

that over 10–24 tons of shells and corals are collected from the reefs per year in an activity that involves ten people collecting once or twice a week (Tomascik et al., 1997).

While the construction industry is a major user of corals in the above-mentioned countries, it is clear that there is wide variation in the exploitation of specific coral products by different countries. These differences are reflected in the total harvest of coral products and also in the site and method of exploitation. In the mid-1990s, in Sri Lanka the greatest proportion of coral rock (42%) was derived from fossil reefs inshore, whereas live coral collection represented 12% and coral rubble (collected from the beach and reef flats) 30% of the total harvest. In India, the collection of coral fragments greatly exceeded the collection of coral 'stones' mainly because of its ease of collection and the reduced demand for the latter. Conversely, in the Maldives coral rock was much more important in the construction industry in the mid-1990s (Figure 1) than coral fragments, while in Tanzania both fossilized limestone and live coral were used in building work.

### Methods of coral extraction

Generally, all living coral is extracted from shallow waters on leeward reef flats and reef edges and in the Maldives from the coral rims of faroes or ring reefs in depths of approximately 2 m of water. The actual choice of sites is dependent on several factors, which include the prevailing weather conditions dictated by the monsoon in the Indian Ocean and the proximity of the final destination of the coral. Throughout South Asia, the manner of harvesting coral rock is very similar, involving manual collection with iron bars (Figure 2). Favored corals include the massive genera *Porites*, *Platygyra*, *Goniastrea*, *Favia*, and

Mining/Quarrying of Coral Reefs, Figure 1 Example of the use of coral rock in construction in the Maldives.

**Mining/Quarrying of Coral Reefs, Figure 2** Mining coral from shallow reef flats in the Maldives.

*Favites* as well as the branching genera *Acropora* and *Pocillopora* (Brown and Dunne, 1988). In the Maldives, the mining of coral rock is carried out by a specific group of islanders from Maamigili in Alifu Atoll working from local fishing craft or dhonis. Corals are broken up and transported to the destination and left for a period in the open for the action of sun and rain to clean the rock of its living inhabitants and leach out the salts (Figure 3). The coral is then broken up into irregularly shaped coral nodules which are the directly incorporated into the building trade. It is estimated that in the Maldives, up until 1988, at least 200 m<sup>3</sup> of coral rock had been removed from reefs in North Male Atoll for use in the construction industry (Brown and Dunne, 1988).

### Biological effects of coral mining

Very similar biological effects of mining were found in two studies, one in the Maldives (Brown and Dunne, 1988; Dawson-Shepherd et al., 1992) and another in Tanzania (Dulvy et al., 1995). The effects included a marked decrease in coral cover and a lack of coral recovery on mined areas several years after coral extraction had ceased and also a reduction in overall abundance and diversity of fish communities across planktivorous, benthic herbivorous, and omnivorous trophic groupings (Brown and Dunne, 1988; Dawson-Shepherd et al., 1992; Dulvy et al., 1995). A loss of rugosity was also noted on mined reefs in the Maldives (Dawson-Shepherd et al., 1992). Butterfly fish or Chaetodontidae, which rely on corals as a source of food, showed marked reductions on mined sites in Tanzania, while in the Maldives, species such as the damselfish *Chromis* spp. were conspicuously absent from mined areas, probably because they depend on the three-dimensional structure of the reef for shelter and also on a pelagic supply of food. One reason for the

poor recovery of these mined reefs lies in the unstable nature of the resulting substrate, which by its mobile nature prevents successful colonization and growth of juvenile corals (Brown and Dunne, 1988; Clark and Edwards, 1994).

### Alternative management options and restoration of mined reefs

A number of alternative management options have been put forward to reduce demand for coral rock in the Maldives, which range from the use of concrete blocks (Figure 4) instead of coral rock to the commercial mining of a single faro reef (Brown and Dunne, 1988, 1995). In Mafia Island, Tanzania, the use of sun-dried mud blocks has been suggested as a replacement for coral products (Dulvy et al., 1995; McClanahan et al., 2000). Stricter legislation has also restricted the amount of coral mined in countries such as the Maldives (Brown, 1977b; Sluka and Miller, 1998), while participatory, collaborative management processes have had some success in Sri Lanka (Brown, 1997b) and Tanzania (McClanahan et al., 2000).

The use of artificial reef structures (concrete blocks and mats or chain link fencing and paving slabs) to promote reef growth on mined reefs is extremely costly but effective (Clark and Edwards, 1994) and while transplantation of corals from elsewhere to such structures has had some success, it is suggested that transplantation should only be undertaken if natural recruitment does not occur (Clark and Edwards, 1995; Edwards and Clark, 1998). The latter authors conclude that where suitable surfaces for settlement are available and water quality is conducive to coral growth, natural recruitment can provide significant restoration within 3–4 years. In the Maldives, stabilizing the substrate with concrete mats has encouraged successful coral recruitment on mined substrates.

Mining/Quarrying of Coral Reefs, Figure 3 Weathering of coral rock prior to its use in construction in the Maldives.

Mining/Quarrying of Coral Reefs, Figure 4 The use of concrete blocks in construction in the Maldives.

### Summary

There is no doubt that coral mining is still carried out within the Indian Ocean but because of legislation and the adoption of more sustainable alternatives, the quantities of corals mined today are much more limited than they were 20 years ago.

## MOATING

Scott Smithers

James Cook University, Townsville, QLD, Australia

### Definition

Moating is the process of constraining the ebbing tide over the reef to produce moats in which low tide water levels remain perched above open water levels (see [Moats](#)).

Moating truncates the lower part of each tidal cycle at an elevation determined by the height (in the tidal frame) and permeability of the moating structure ([Figure 1a](#)). Moating can occur at any intertidal elevation and may only be active during the lowest spring tides.

Where moating occurs behind stable and impervious features, like algal rims (see [Algal rims](#)) the water level is consistent on every (lower) low tide. In contrast, at mesotidal locations like the central Great Barrier Reef (GBR) open water spring and neap low tides can differ by > 2 m.

Moating allows some reef biota to survive above their open water limits, and must be considered when

**Moating, Figure 1** (a) shows how moating above the low tide level, modifies the tidal curve and allows intertidal biota to survive above their open water limits. Moating occurs behind structures like these algal terraces on the reef flat at Bewick Island, northern GBR (b).

interpreting intertidal sea-level indicators, especially coral microatolls (see [Microatoll](#)) ([Figure 1a](#)). Moating also has important implications for sedimentation on reefs. It controls the tidal windows when tidal currents are active, and modifies reef flat depths and thus where reef top waves may entrain and transport sediments.

## MOATS

---

Scott Smithers  
 James Cook University, Townsville, QLD, Australia

## Synonyms

Ponds; Reef top pools

## Definition

Moats are areas of water held over intertidal reef surfaces above the open ocean level during lower tides. Moats form when ebb-tide drainage is impeded behind biologically constructed or sedimentary structures. The former includes reef crest algal rims and algal terraces. Sedimentary structures include storm ridges or ramparts (commonly of coral shingle) and minor ridges of sand and gravel. Shallow moats may also pool in subtle reef flat depressions.

Moats behind algal rims can be impressive, impounding water well above the ocean tide, especially in areas of high tidal range. For example, a high algal rim extending > 2 m above the MLWS tide level encircles Redbill Reef on the central Great Barrier Reef, and holds water just 8 cm below MSL during low tides (Hopley, 1982). Moats of this type may cover several km<sup>2</sup>. Smaller algal terraces are common on the seaward slopes of algal rims and form shallower (< 20 cm) moated ponds typically 1–100 m<sup>2</sup> in size.

Moats confined by sedimentary structures may be less permanent in their construction and effect. For example, unconsolidated rubble and shingle ramparts tend to leak initially and are vulnerable to reworking. Although water remains moated above open water, small breaches can episodically lower water levels. Over time compaction, infill of voids with finer sediments, and basal cementation may improve the damming efficiency of these structures, but usually at a lower height than immediately post-emplacement.

Moats occur on most reef flats but are best developed where the tidal range is large, algal rims thrive, and coral growth and storm frequency provide enough rubble and depositional events. Emergent back reef, as produced by late Holocene relative sea level fall, is also excellent substrate for moat development.

Moats are important habitats that may support a diverse reef flora and fauna above the ocean low tide level. Moderately sized and cemented/encrusted moats are more physically stable and typically harbour the most diverse communities, especially where moat water is well flushed daily. Small shallow moats tend to be less permanent, and are vulnerable to biologically limiting thermal and salinity extremes.

Several other features are referred to as moats with varying degrees of correctness. Moated boat channels – containing water of navigable depth – occur on some reef flats, either immediately behind algal rims where surging waves and sediment flux limit reef growth or, on fringing reefs, nearer to the shore where terrestrial runoff achieves the same effect. Although in each case water may moat behind the algal rim, the deeper water is chiefly a function of locally restricted vertical accretion rather than ponding over the reef flat. Maldivian cay shorelines oscillate with monsoonal reversals and similarly constrain upward reef growth near the cay below that of the reef edge. The deeper zone separating the reef rim and cay formed by this process has also been called a moat.

## MOLLUSCS

---

José H. Leal  
 The Bailey-Matthews Shell Museum, Sanibel, FL, USA

## Definition

The Mollusca are soft-bodied animals that usually have a hard, protective shell. They constitute the most diverse marine phylum and the most diverse group of coral-reef organisms (Paulay, 1997). Coral reefs provide substrata, protection, and food for molluscs (Caterall, 1998; Morton, 1983). In turn, molluscs influence reef growth and internal biological processes. Some gastropods prey directly on live coral tissue, causing, in some cases, a significant

impact in structuring of reef communities. Bioerosion of live coral skeletons and coral rock alters and destroys, ultimately reducing them to fine, unconsolidated sediments. Bioeroders may be divided into the epilithic and the endolithic (Glynn, 1997). Using their reinforced radular teeth, epilithic bioeroders abrade limestone in the process of grazing on algae or other organisms. These include chitons, patellids, trochids, littorinids, and neritids (Glynn, 1997). Endolithic bioeroders bore into coral skeletons using chemical and/or mechanical processes. Bivalves in the genera *Lithophaga*, *Gastrochaena*, *Fungiacava*, and *Choristodon* are active borers, whereas *Tridacna* and *Hippopus* show a limited degree of downward penetration (Glynn, 1997; Morton, 1983). Reef-building vermetid gastropods in the genera *Vermetus* and *Dendropoma* can be important contributors to the structure of coral reefs.

## MURUROA ATOLL

Lucien F. Montaggioni  
University of Provence, Marseille Cedex 3, France

## Definition

The atoll of Mururoa, also known as Moruroa or Aopuni, lies in the south-eastern end of the Tuamotu Island Group (21°50'S, 138°53'W) in the central Pacific. Politically speaking, this island is part of the French Polynesia.

## Geological setting

Mururoa is 28 km long and 11 km wide with a reef rim not exceeding 15 km<sup>2</sup> in surface area. It falls into the open-atoll type with a large natural pass (4,500 km wide, 1–9 m deep) on its leeward side. Its volcanic basement has originated from the Pitcairn hotspot at present operating about 70 km to the south-east of Pitcairn Island (Gillot et al., 1992). The cessation of volcanic activity

from about 11 to 10.5 million years favored prominent reef building. Subsidence of the volcanic shield at an average rate of 7–8 mm per millennium has been accompanied by deposition of a sedimentary pile varying between 130 and 570 m thickness (Buigues, 1997). From the end of the 1960s, in relation to nuclear testing, intensive biological, geological, and geophysical surveys were carried out on the modern reef and its carbonate foundations.

## Modern reef morphology and zonation

The reef zonation, the composition and distribution of major reef-building biological assemblages have been described by Chevalier et al. (1969), Bablet et al. (1995) and Camoin et al. (2001). Up to 50 coral species have been described from the fore-reef to lagoonal areas.

### The outer reef rim

The reef rim, 3 m in maximum elevation, consists of successive islets (« motus ») that form a continuous 400-m wide line along the windward side, and a discontinuous line, 1,100 m wide on the leeward side. The rim is made up of coral rubble mixed with skeletal sand, locally resting on the modern reef flat or overlying emergent, firmly cemented coral conglomerates of mid-to late Holocene age. The reef-flat zone is subdivided into three subzones. The outermost subzone is a typical algal ridge, up to 0.50 m high, 20–50 m wide, mostly made up of coralline algal crusts (*Hydrolithon onkodes*, *Chevaliericrusta polynesiae*) associated with encrusting foraminifera (*Homotrema*, *Acervulina*) and scarce robust branching corals (*Acropora humilis*, *Pocillopora verrucosa*). Behind the algal ridge, there is a coral-dominated subzone inhabited by stunted branching, massive, and encrusting colonies (*A. humilis* group, *Pocillopora brevicornis*, *Favia stelligera*, *Montipora caliculata*, *Porites lichen*). Behind the islets to the lagoon, there is an inner reef-flat subzone mainly covered by loose detritus and a few corals (*Acropora muricata*, *A. corymbosa*, *A. microphthalma*, *A. tenuis*, and *Alveopora allingi*).

The fore-reef zone can be delineated into three subzones. The upper subzone (to about 10 m deep) is gently dipping (less than 15°) and dominantly colonized by robust branching and massive corals (*Acropora robusta* group, *A. humilis* group, *P. verrucosa*, *P. eydouxi*, *F. stelligera*, *Platygyra daedalea*). Between the depth of 10 and 40–50 m, the intermediate fore-reef subzone becomes increasingly steeper (30–45°). The coral cover rate decreases; the dominating coral species include *Acropora nasuta*, *Astreopora myriophthalma*, *Leptastrea transversa*, *Echinopora gemmacea*, *Leptoria phrygia*, *Pocillopora elegans*, together with *Montipora* and *Cyphastrea*. The lower fore-reef subzone below 40–50 m forms a sub-vertical drop-off, locally covered by encrusting, tabular, and foliaceous corals (agariciids mainly) associated with coralline algae and encrusting foraminifera (acervulinids). In addition, the fore-reef zone exhibits terraces at 10, 20, 40, 55, and 65 m and cave-like

features at 80, 90, 100, and 150 m deep (Buigues, 1997). The terraces were interpreted as former tops of successive reef units deposited during the late Pliocene and the Pleistocene, while the caves may have been the result of dissolution controlled by colder, interstitial reef waters or by meteoric waters during former low sea stands.

Locally, brackish ponds form in shallow reef-rim depressions (Trichet, 1969) and contain cyanobacterial communities. These develop as mats (matolites or « kopara » according to Défarge et al., 1994) in which calcareous microbialites and phosphorites are deposited (see Richert et al., 2006 for review). These processes are thought to be promoted by nutrient-rich, thermally driven convective currents within the carbonate pile (i.e., the endo-upwelling concept of Rougerie and Wauthy, 1993).

### The lagoon

It averages 30–40 m depth and contains numerous reef patches. Coral communities on both lagoonal floor and patches consist chiefly of arborescent *A. muricata* group, *A. pulchra*, massive *Porites lobata*, *Leptastrea purpurea*, *Favia speciosa*, and branching *P. verrucosa*.

### Lithology and structure of the sedimentary pile

During the building of the volcanic shield, submarine eruptive events close to the sea surface have alternated with episodes of coral settlement, resulting in coral-rich layers embedded into the volcanic rocks. The deepest occurrence of carbonate deposits is about 950 m beneath the modern rim surface. The volcanic rocks are overlain by a sedimentary pile that comprises two distinct series: a basal volcanoclastic series and a carbonate cap. The entire pile displays a number of seismic reflectors identified in cores as unconformity surfaces at the top of different diagenetic units (Buigues, 1997).

### The volcanoclastic series

It ranges between 100 and 0 m in thickness from the periphery to the center of the atoll. The series is typified by the superimposition of transgressive (retrograding) depositional sequences. At base the sequences are usually composed of volcanic conglomerates. Progressively upwards, the volcanoclastics decrease in grain size and thickness to thin sand beds. Correlatively, coral-derived material increases in volume, locally forming massive buildups trapped into the volcanoclastics. The younger volcanoclastics are found at around 300 m below the modern reef rim.

### The carbonate cap

It occurs between 300–500 and 120–220 m beneath the reef rim and the center of the atoll respectively. An array of reef-related facies has been identified and includes corallgal framstones and bindstones, with skeletal rudstones to grainstones typical of high-energy, outer rim environments; coral bafflestones associated with skeletal

floatstones to wackestones, characteristic of low-energy environments; coral platstones to sheetstones embedded into wackestones to mudstones, typical of sheltered, lagoon-like environments. The spatial distribution of these facies reveals that the carbonate system has evolved in terms of morphology and architecture over time. The development history of the carbonate cap has been reconstructed on the basis of age determinations, i.e., radiocarbon, uranium-series, and magnetostratigraphy (Buigues, 1997). The settlement of fringing and barrier reefs is likely to have been discontinuous throughout the Miocene, primarily controlled by volcanic activity and, from about 10.5 million years by residual volcanic topography, tectonics, and sea-level changes. The entire volcanic basement has been capped by an extensive flat-topped carbonate platform probably not prior to the Pliocene. The classical atoll morphology is thought to have been acquired during the late Pliocene to Pleistocene. This results from both dissolution in the central platform areas and lateral reef accretion at the periphery in response to changes in sea level (Perrin, 1990; Buigues, 1997; Camoin et al., 2001). From top to base, the carbonate cap is composed of four stratigraphical units. The Holocene reef unit ranges between about 4 and 20 m in thickness. The Pleistocene reef unit is about 50–150 m thick. It displays major unconformity surfaces at 10, 30, 65, 80, and 90 m below present reef surface, separating successive reef generations. The Pliocene reef unit ranges from about 70 to up to 150 m in thickness. The oldest unit (Late Miocene) locally exceeds 150 m in thickness (Figure 1).

### Carbonate diagenesis

The carbonate rocks from both the volcanoclastic series and carbonate cap have suffered severe diagenetic alteration (replacement by low-magnesium calcite and dolomite, dissolution, karstification) probably controlled by freshwater aquifers in relation to changes in sea level (Aissaoui et al., 1986). There is a significant increase especially, both in calcite and dolomite diagenesis towards the periphery of the carbonate cap. Apart from the upper 20 m (Holocene) composed of metastable minerals (aragonite, high-magnesium calcite), the cap contains low-magnesium calcite or dolomite. The dolomite unit probably of late Miocene Age, occupies the lower two-thirds of the carbonate cap (Figure 1). Dissolution is one of the most prominent diagenetic features in the carbonate cap. The whole series appears to be severely karstified. Karst starts at 90–100 m and extends down to 150 m within the Pleistocene carbonates, both beneath the rim and the lagoon. Large-scale karstic surfaces also occur 180–200 m deep at the Pliocene–Miocene transition and 220–280 m and 300–350 m deep at the base of the Miocene carbonates.

### Pleistocene reef growth and sea-level changes

Uranium-series age determinations of the successive reefs units drilled through the outer rim at Mururoa provide new

**Mururoa Atoll, Figure 1** Lithology and structure of the carbonate cap with special reference to the outer reef rim over the last 300 ka, Mururoa Atoll, French Polynesia. *HO* Holocene unit, *PLE* Pleistocene unit, *PLIO* Pliocene unit, *MIO* Miocene unit. Numbers 1–12 refer to Marine Isotope Stages (MIS). Modified from Buigues (1997) and Camoin et al. (2001).

constraints on reef physiography and variations in sea level during the past 300 ka (1 ka = 1,000 years) (Perrin, 1990; Camoin et al., 2001). The outer rim has developed seawards in the form of a series of overlapping fringing reefs (Figure 1). Estimates of former sea-levels are based on the age-depth relationship of selected corals with correction of the present depth for both thermal subsidence of the atoll and habitat-depth range of the corals. Prominent reef units primarily made up of corallgal boundstones have developed during four episodes of high sea stands (MIS stages 1, 5, 7, and 9). The data indicate that sea level was between 17 and 23 m below present sea level (bpsl) at 9 ka. During MIS stage 5 e (around 125 ka), sea level is estimated to have been 6–10 m above present reef surface. The paleo-sea levels at 212 ka (stage 7 c) and 332 ka (stage 9 c) were 11–17 m 26–33 m bpsl respectively. Low sea stands are typified by limited reef growth and large skeletal deposition and include MIS stages 2, 4, and 8. During stage 2 (Last Glacial Maximum), sea level was around 135–140 m bpsl within the 23–17 ka interval. The paleo-sea level during stage 4 at around 60 ka is assumed to have been between 76 and 91 m bpsl, while it was at 79–94 m bpsl during stage 8 d at about 270 ka.

## Summary

Mururoa is an open atoll and exhibits low coral diversity (about 50 species). Drilling investigations revealed that the maximal thickness of the carbonate pile ranges between 500 and 220 m. The lowermost part of the pile is late Miocene in age. The typical atoll morphology is likely to have been acquired not before the late Pliocene. During the Pleistocene, and especially the last 300 ka, the outer rim has accreted seawards through a series of

stacked fringing-like reef bodies. The carbonate deposits have experienced intense diagenetic alteration by fresh water during successive low sea stands.

## NEW CALEDONIA

---

Guy Cabioch  
IRD (Institut de Recherche pour le Développement),  
Bondy, CEDEX, France

### Introduction

New Caledonia is located in the South West Pacific Ocean and comprises several islands and islets and a broad diversity of oceanic and continental reef structures including (non-exhaustive list) shoals, atolls, uplifted reefs, drowned reefs, patch reefs, fringing reefs, and barrier reefs (Andréfouët et al., 2009). In the recent review by Andréfouët et al. (2009), the mapping by high spatial resolution optical remote sensing data indicated that the 161 unit types of the New Caledonian coral reef complexes were distributed across 4,537 km<sup>2</sup> of reef area and 31,336 km<sup>2</sup> of non-reef area. More specifically, between the coastlines of the main island, called the Grande Terre, and the barrier reef, a more or less wide lagoon of approximately 30 m depth extends along both sides. The Grande Terre is bordered along the 500-km-long coastline by one of the longest barrier reefs in the world (1,600 km), double or triple in several parts (Guilcher, 1988), interrupted by passes, often in front of rivers, and by drowned segments, especially along the east coast. This barrier reef extends northward, enclosing the North lagoon and the Belep islands; it also extends southward, enclosing the south-west lagoon or lagoon of Nouméa enclosing several coral islets and the Ile des Pins (Figure 1). The coastlines of the Grande Terre are bordered by fringing reefs particularly well developed on the east coasts while mangroves alternate with fringing reefs on the west. For instance, our knowledge on the development and history of coral reefs in New Caledonia is focused on the Grande Terre and

Loyauté islands. Little is known regarding the reef evolution of the shoals, atolls, and drowned reefs.

### Climatic conditions

Two marked seasons can be reported: (1) from November to April during the austral summer, the climate is tempered by the prevailing southeast trade winds and (2) from May to October, during the austral winter, the trade winds are disturbed by westerlies generated by polar air masses. Moreover, New Caledonia can be affected by tropical cyclones from November to May with some damages to reefs as recently reported (Guillemot et al., 2010). Due to its location, New Caledonia is in the south of the West Pacific Warm Pool (WPWP) under the influence of the interannual climatic variations resulting from the El Niño Southern Oscillation (ENSO) phenomenon. In this region, the fluctuation of the south branch of the Intertropical Convergence Zone (ITCZ), the South Pacific Convergence Zone (SPCZ), is marked by variations in the oceanographic parameters. During the “La Niña” events, New Caledonia experiences high rainfall and variations in sea surface salinities (SSS) (Delcroix and Lenormand, 1997). During the last decades, ENSO events and climatic variability were investigated using analyses of isotopes ( $\delta^{18}\text{O}$ ) and trace elements (Sr/Ca, U/Ca, Ba/Ca) at a monthly resolution on corals, to reconstruct the past sea surface temperatures (SST), SSS and nutrient inputs (Beck et al., 1992; Quinn et al., 1996, 1998; Corrège et al., 2001; Stephans et al., 2004; Ourbak et al., 2006; Delong et al., 2007).

### Geological setting

New Caledonia is located on the Australian tectonic plate, which dips beneath the North Fiji Basin microplates and Pacific tectonic plate. The subduction zone (Vanuatu trench) is situated eastward of the Loyauté islands (Figure 1). The resulting deformation of the Australian

**New Caledonia, Figure 1** (a) The south west Pacific showing the plate boundary and the location of New Caledonia, Vanuatu archipelago, Solomon islands, Papua New Guinea, and Australia. (b) The mainland of the Grande Terre of New Caledonia, the Loyauté islands, "île des Pins," and the d'Entrecasteaux reefs (modified after Cabioch et al., 1996). The coral reef line is reported from Andréfouët et al. (2009).

plate, the lithospheric bulge, can be observed in the variations of altitude of the uplifted atolls of the Loyauté islands (Dubois et al., 1974, 1975; Guyomard et al., 1996). Globally, it appears that the morphology and the distribution of coral reefs in New Caledonia highly depend on the vertical motions (Chevalier, 1968; Cabioch et al., 1996) so that their morphological studies and the coral datation provide data on the neotectonics in the Late Quaternary. In this way, the study of the variations in depth or altitude of the 125 ka (1 ka = 1,000 years) reefs (generally expected at +6 m above the modern sea surface) and the modern reefs documents on the differential vertical movements and the recent motion rates. The overall setting of the 125 ka reef around New Caledonia shows an irregular increasing island subsidence tendency northward and southwestward from a relatively more or less central zone (Cabioch et al., 1996). For instance, Frank et al. (2006) show that the Amédée reef, in the southwest (Figure 1),

subsided at a rate of at least  $0.16 \text{ mm y}^{-1}$ , while the reefs close to the coast, for example, as at Nouméa, subsided at  $0.07 \text{ mm y}^{-1}$ . Subsidence is also low,  $0.03 \text{ mm y}^{-1}$ , near Bourail in the West. It appears that the highest subsidence rates were observed offshore explaining the formation of the wide southwest and North lagoons. The modern coral reef growth and reef morphology are also affected by the hydro-isostasy effects. This is the reason why around the Grande Terre, some raised beach-rocks, abraded reef flats and microatoll corals exposed up to more than 1 m above the modern sea level, dated of the mid-Holocene, can be found (mid-Holocene). These morphological features and reef structuration are dependent on the hydro-isostatic readjustment consequently to the last deglacial sea level rise from  $-120 \text{ m}$  to the modern sea level and depending on the underlying mantle viscosity (Cabioch et al., 1996). Such a process also explains the distribution and the morphological variations of the modern coral reefs and coastlines.

## History of coral reefs and lagoons

The development of the New Caledonian fringing and barrier reefs and the nature and distribution of their biofacies were documented by several studies performed on cores made mainly around the Grande Terre (Coudray, 1976; Fontes et al., 1977; Cabioch et al., 1995, 2008; Cabioch, 2003). These cores are composed of alternating layers of coral and coralline algal frameworks, detrital facies, sands, and gravels. Moreover, these cores revealed that the fringing reefs are characterized by the succession of two reef generations, while the barrier reefs by several reef or carbonate unit generations, all separated by unconformities resulting of emersion during the low sea stands. It appears that the reef growth results from the combination of both tectonic and climatic factors. The history of the lagoons is not well known, but recent bathymetric and seismic surveys documented our knowledge on the structure of the southwest lagoon.

## Fringing reefs

In the fringing reefs of the Grande Terre, coral dating in 37 cores, drilled along perpendicular or parallel transects on the reef flat, shows that the initiation growth stage is generally missing and that the reefs started to grow very quickly and suddenly (Figure 2) (Cabioch et al., 1995).

In the south, the growth started prior to 5 ka BP upon old reef karstic formations and in the north after 4.2 ka BP, generally upon non-carbonate rocks, mainly metamorphic rock (Cabioch et al., 1995; Cabioch, 2003). These differences in initiation age would be explained by unavailable suitable foundations and also as resulting from colonization of various types of substrates, the karstic limestone surfaces being probably the most suitable substrate for coral-larval and attachment recruitment. Core analysis also shows that framework, generally, dominates over skeletal debris in the higher energy reefs, while skeletal debris are the main components in the lower energy reefs (Cabioch, 2003). Moreover, the branching and tabular coral assemblages (acroporids) are mainly developed during the early stages of reef growth, whereas the domal (faviids, poritids) and/or robust-branching (acroporids) assemblages appeared later (Figure 2). Unfortunately, the reef slope and front edge zones were not investigated by coring so that two interpretations were proposed to explain this observation (Cabioch, 2003): a progressive succession from low-energy to high-energy water environments interpreted as a progressive increase of water energy as the reef approaches the sea surface, typical of a catch-up reef growth mode (Growth classification and sea level); or alternatively, a transition from lagoonal deposits typified by coral and skeletal debris to reef coralgal biofacies interpreted as a reef initiation, retrograded over its back-reef. Examination of the distribution of reef facies from reef to reef also provides additional information and shows a strong relationship with the antecedent topography (Antecedent platforms) and the local water-energy conditions. The high water energy

reefs characterized by steeply dipping antecedent platforms are dominated by frameworks while medium water energy reefs by abundant reef detritus.

## Barrier reefs

The history and the development of barrier reefs in New Caledonia are less known because it is more difficult to drill in the barrier reef tracts strongly exposed to the oceanic conditions. One of the first studies was performed by Coudray in 1976 at Ténia, on the west coast (Figure 1). Analysis of the 226 m-long core revealed the occurrence of several episodes of reef development during several interglacial quaternary stages. More recently, cores recovered at Amédée in the southwest and Kendec in the northwest (Figure 1) (Cabioch et al., 2008) showed that the New Caledonian barrier reefs are composed of a succession of depositional units resulting from a combination of glacio-eustatic sea level variations and subsidence (Antecedent platforms). In both areas, 11 carbonate units deposited during the high sea stands are observed, separated by unconformities resulting from emersion during the glacial periods (low sea stands). It appears that the reef growth would have begun around 400 ka in marine isotope stage 11, considered as a particularly favorable period for coral development. Prior to this period, the carbonate units are not characterized by biofacies typical of coral reefs *sensu stricto* although scarce isolated corals can be found.

## Lagoon

Lagoons are the transition between the two morphological features of the fringing and barrier reefs, but their history is still little known. Nevertheless, a recent high resolution seismic and multibeam surveys of the South-West lagoon (Figure 1) has revealed several depositional sequences bounded by erosional unconformities, indicating two periods of deposition and erosion in the past 200 ka (Leroy et al., 2008). Two generations of incised deep fluvial valleys, connected by passes to the continental slope, were identified. These data would indicate that the lagoonal history does not extend beyond 200 ka. In addition, the analysis of morphology of this network of drainage suggests a progressive south-westward tilt of the outer lagoon expressing the role of tectonics in the formation of the lagoons.

## Climatic and/or oceanographic factors affecting the reef growth and the coral development

The distribution and the growth of modern fringing and barrier reefs are dependent not only on the tectonic context but also on the climatic variations. The climatic variations at the scale of the last 100,000 years (astronomical theory), marked by sea-level variations of the glacial and interglacial periods, influenced the internal structure and reef succession in the barrier reef tracts (see above the history of Barrier reefs). At the scale of the Holocene, the oceanographic factors and climatic variations influenced on the initiation and growth of both barrier and fringing reefs.

**New Caledonia, Figure 2** Typical biofacies from selected cores performed in the fringing reefs of the Grande Terre (modified after Cabioch et al., 1995; Cabioch, 2003).

Montaggioni et al. (2006) concluded that the upwellings seem to have been more active than today at about 6 ka, marked by occasional brief cooling events, while the SST was 1°C higher than now, explaining that the retardation of the reef development in the southwest areas of New Caledonia. It appears that nutrient supply from upwelling may have a major role in the control of the reef growth.

### Summary

New Caledonia is characterized by a broad diversity of continental and oceanic reef structures, but at this day,

only the growth history of fringing and barrier reefs from the main island or Grande Terre was intensively investigated and relatively well known. It appears that the morphology and the distribution of modern reefs can be explained by several parameters: (1) the nature and the morphology of the antecedent topography resulting of both vertical motions and climatic factors; (2) the growth pattern depending on variations of local ecological factors and oceanographic factors including SST and SSS data and also the nutrient supply from upwellings. Moreover, this region appears to be a key region to analyze the reef

episodes of the various interglacial periods. Studies from two sites in New Caledonia showed that the coral reefs probably flourished only since 400 ka.

## NOTCH AND VISOR

Stephen Trudgill  
 University of Cambridge, Cambridge, UK

## Definition

A notch is a horizontal intertidal recess in a solid coastline. The upper rock protruding over the recess below gives rise to the allusion to a “visor” as it can appear to be like a raised opened visor on the helmet of a suit of armor ([Figure 1](#)).

**Notch and Visor, Figure 1** Notch and visor from Aldabra Atoll, Indian Ocean (Photo: S.T. Trudgill).

Two conditions are necessary for the formation of a notch (1) a focus of erosive agencies in the intertidal and (2) relatively sheltered conditions because on high-energy coasts wave action would tend to act to remove the upper projecting rock. The erosive agencies may involve abrasion by sand, especially in the lower part of the notch but generally involve bioerosion by boring organisms, such as sponges and bivalve molluscs, which bore into the rock to avoid desiccation and organisms which graze on epi- and endolithic algae such as chitons and gastropod molluscs. These are focused in the intertidal zone as it is too dry for them to survive above and they tend to be outcompeted by other organisms below, hence giving greater erosion in the intertidal zone and the notch.

## NUTRIENT POLLUTION/EUTROPHICATION

---

Katharina Fabricius  
 Australian Institute of Marine Science, Townsville, QLD,  
 Australia

### Synonyms

Eutrophication; Nutrient pollution; Organic enrichment

### Definition

Eutrophication defines the process of increasing the rate of supply of plant nutrients (especially nitrogen and phosphorus) and organic matter to an ecosystem. A contaminant is defined as a substance (including nutrients and sediments) that occurs above “natural” concentrations, while the term “pollutant” defines a contaminant that occurs at a concentration that causes environmental harm (e.g., changes in physical, chemical, or biological properties; biogeochemical functions; and/or biological community structures of a system).

### Summary

Nutrient pollution or eutrophication has severely degraded many coastal reefs around the world. The three main pathways of reef damage by nutrient pollution are release of nutrient limitation (nitrogen, phosphorus, or organic matter), light limitation from increased turbidity, and flow-on effects from altered sediment properties. While nutrients, light, and sediments also vary greatly in areas unaffected by humans, they are often elevated from land clearing, agricultural and urban runoff, and aquaculture. Eutrophication leads to reduced recruitment and species richness in reefs and altered trophic structures (corals being replaced by macroalgae in shallow water and by heterotrophic communities in deeper water). On Indo-Pacific reefs, nutrient pollution may also lead to increased frequencies of outbreaks of the coral-eating starfish, *Acanthaster planci*. The vulnerability of a specific reef area to damage by eutrophication is greatest if it is located in a poorly flushed location or surrounded by a shallow sea floor. Reefs that are frequently disturbed and reefs with low abundances of herbivorous fishes are also sensitive to degradation by nutrient pollution. In contrast, reef areas that are flushed by fast currents or surrounded by a deep

water body and reef areas with abundant herbivores are relatively resistant to exposure to nutrient pollution.

### What is eutrophication?

Eutrophication, or nutrient pollution, is defined as the process of enrichment of waters with plant nutrients and organic matter, often resulting in a chain of trophic changes. Eutrophication is typically caused by the elevated supply and availability of the macronutrients nitrogen (N) and/or phosphorus (P), which stimulate the growth of microbes, micro- and macroalgae, and lead to an increased supply of organic matter. This in turn alters the physical and chemical environment by reducing water clarity and organically enriching sediments and eventually results in potentially profound changes in biogeochemical, physiological, and ecological conditions. If the nutrients and sediments leading to eutrophication occur at a concentration causing such environmental harm, they fit the definition of “pollutants.” Minor cases of eutrophication, i.e., if they occur at above “natural” concentrations without causing environmental harm, they fit the definition of “contaminants.” Nutrient pollution is only one of the many forms of aquatic pollution, others being pollution by pesticides, industrial effluents, pharmaceuticals, oils spills, fecal bacteria, etc., which are not being covered here. Nutrient levels can also be quite high in some undisturbed ecosystems, yet when human activity elevates nutrients in environments with naturally low nutrient availability, the resulting conditions may be far removed from natural equilibria. The relative trophic state of aquatic ecosystems is sometimes classified as “oligotrophic” (low nutrient availability), “mesotrophic,” or “eutrophic” (relatively high nutrient availability, either naturally or from nutrient pollution). This classification is only of limited use and should only be applied when comparing within ecosystems’ types, because a eutrophic lake typically has far higher nutrient concentrations than a eutrophic coastal marine water body. However, it is important to understand that all of these ecosystems may be subject to eutrophication, i.e., an anthropogenic enrichment with nutrients compared to their previous state. Due to its cascading effects on ecosystems and the incremental changes from natural overcontaminated to polluted conditions, the question of nutrient pollution is very complex and broad in scope.

Well-described symptoms of eutrophication are increased phytoplankton production, bacterial and fungal growth, an increased frequency of visible algal blooms (such as red tides) or marine snow aggregates, and/or the massive development of attached and/or floating algal mats (Vollenweider, 1992). Further, water transparency is often reduced from suspended detritus, mineral particles, and plankton, and dissolved oxygen levels in the bottom waters may be depleted and can cause fish kills. Economic consequences attributed to severe eutrophication include a reduction in the health of shellfish, fish, and benthos; reduced tourism; ciguatera shellfish

poisoning; and potential effects on human health from dermatitis or conjunctivitis (Vollenweider, 1992). However, the symptoms of eutrophication are not always consistent and predictable across the World’s aquatic ecosystems.

Eutrophication is usually caused by the excessive runoff of fertilizers from farms, soil-bound nutrients from cleared lands, sewage effluents, or discharges from aquaculture into a poorly mixed or partly enclosed water body. The amount of nutrients and sediments lost from a catchment is well predicted by its geographic features including soil type, slope angle, and rainfall. Additionally, soils and fertilizers flow from cleared and overgrazed lands, sewage, or aquaculture farms into coastal marine ecosystems, including coastal coral reefs (Vitousek et al., 1997; Tilman et al., 2001; Smith et al., 2003). Globally, the use of nitrogen fertilizer has increased more than 6-fold since 1960 (Matson et al., 1997), and an additional 1% of the earth’s surface is being cleared every year. About 45% of the global human population ( $\sim 100$  people  $\text{km}^{-2}$ ) are now living in coastal areas, and human population is growing even faster along the coast than elsewhere: the number of people living in the coastal area has increased by 765 million to  $\sim 3.1$  billion people since 1990 alone (Crossland et al., 2005). All this contributes to increasing losses of nutrients from the land and a rapidly intensifying exploitation of coastal resources (Crossland et al., 2005). Oxygen-depleted seafloor zones, attributable to runoff of agricultural nitrogen and phosphorus, have doubled in area in the last few decades – indicating that many marine water bodies are becoming more eutrophic (Diaz and Rosenberg, 2008; Vaquer-Sunye and Duarte, 2008).

### Effects of nutrient pollution and eutrophication on coral reefs

Coral reefs can be found in nutrient, light, and sedimentation conditions that may vary, both spatially and temporally, by 1–2 orders of magnitude even in undisturbed settings. New dissolved and particulate inorganic and organic nutrients and sediments may originate from rivers, the upwelling of nutrient-rich deeper water bodies, nitrogen fixation by benthic and pelagic cyanobacteria and algae, diffuse coastal runoff, groundwater seepage, and rain and settling dust from the atmosphere. Reef communities naturally change with nutrient, light, and sedimentation conditions: from terrestrially influenced conditions (characterized by fluctuating salinity, more variable or higher nutrient load, siltation, and turbidity) to oceanic conditions where nutrients, siltation, and turbidity are typically low. Reef environments are not typically classified by their trophic state (i.e., oligo-, meso- or eutrophic), but reefs in all trophic states may be affected by eutrophication.

Coral reefs are built by the calcium carbonate skeletons of hard corals (order Scleractinia), which live in symbiosis with endosymbiotic unicellular algae (zooxanthellae). The tens of thousands of species associated with coral reefs

depend on the structural complexity derived from coral skeletons, and the ecological condition of coral reefs is, therefore, a direct function of the physiological health of hard corals. Hard corals are highly competitive in low-nutrient environments, for three reasons. First, they are remarkably efficient in internally recycling nutrients between host and zooxanthellae. Second, they occupy most trophic levels simultaneously (Houlbreque and Ferrier-Pages, 2009): the photosynthesis of the zooxanthellae makes them efficient phototrophs; they can absorb dissolved nutrients, graze on large phytoplankton, prey upon zooplankton, and feed on detritus and other decompositional material (Rosenfeld et al., 1999). Third, some species of hard coral can rapidly adapt to varying light and food availability, maximizing energy gains throughout their lifetime (Anthony and Fabricius, 2000). Despite the high adaptability of corals to a range of environmental conditions, reports of coral reef degradation from eutrophication exist from many places around the world (reviewed in Fabricius, 2005). However, the natural variability in background conditions and the paucity of historical data make it often difficult to ascertain causal relationships between eutrophication and reef degradation. Furthermore, other disturbances (e.g., overfishing, coral bleaching, storms, and floods) complicate the assessments. Epidemiological tools originally developed to assess the weight of evidence that smoking causes lung cancer (U.S. Department of Health, 1964) have now been applied to coral reef studies to create a causal link between reef degradation and increased exposure to nutrient pollution in the central Great Barrier Reef (Fabricius and De'ath, 2004).

Eutrophication degrades coral reefs through three pathways (a) trophic changes from the increased availability of nutrients and organic matter; (b) decreasing light availability in deeper water; and (c) altered sediment properties. The following sections briefly review the available information on how these three pathways, alone and in combination, directly and indirectly affect corals, other reef-associated organisms, and the ecological balances of coral reef ecosystems.

### Effects of the increased availability of nutrients and organic matter

Eutrophication increases the availability of nutrients and organic matter both in the water and in the sediments. Dissolved and particulate and organic and inorganic nutrients are often treated separately, as their biological effects differ fundamentally. For example, dissolved inorganic nutrients such as phosphate, nitrate, and ammonium are highly bioavailable and therefore get quickly depleted, whereas many forms of dissolved organic nutrients are largely unusable as food even for bacteria and therefore often accumulate to high concentrations. However, cycling between the different forms of nutrients is fast and complex, due to uptake, excretion, and decomposition in benthic and pelagic food webs that ensure continuous

conversions between dissolved and particulate and between organic and inorganic forms of nutrients.

Studies of eutrophication effects on corals have often focused on enrichment with dissolved inorganic nutrients (e.g., Stambler et al., 1994; Dubinsky and Stambler, 1996; Koop et al., 2001; Szmant, 2002). Exposure to dissolved inorganic nitrogen may lead to declining calcification, higher concentrations of photopigments (affecting the energy and nutrient transfer between zooxanthellae and host; Marubini and Davies, 1996), and higher rates of coral diseases (Bruno et al., 2003). In areas of nutrient upwelling or in heavily polluted locations, chronically increased levels of dissolved inorganic nutrients may alter coral physiology and calcification, causing noticeable changes in coral communities (Birkeland, 1997). However, although high levels of dissolved inorganic nitrogen and phosphorus can cause significant physiological changes in corals, they do not kill or greatly harm individual coral colonies (reviewed in Fabricius, 2005). Furthermore, biological uptake by bacteria, phytoplankton, and the benthos rapidly convert dissolved inorganic nutrients into particulate organic matter (especially detritus, bacteria, phytoplankton, and marine snow), hence their concentrations in the water column are often low even in areas of eutrophication.

The main pathway how dissolved inorganic nutrients affect coral reefs is by organic enrichment of suspended particulate matter and sediments. Pelagic particulate organic matter is often measured using chlorophyll, total suspended solids, and/or particulate nitrogen and phosphorus as proxies. Particulate organic matter may alter benthic irradiance, may organically enrich sediments, and may lead to hypoxia in sediments. These secondary effects are, additionally to nutrient enrichment, significant eutrophication effects. Particulate organic matter is used by corals as food, and their tissue thickness, photosynthetic pigment concentrations, and calcification increase in response to feeding on particulate organic matter. At moderate levels of eutrophication, some hard coral species can compensate for lost photosynthetic carbon gains by increasing particle feeding, while other species become saturated at low particle concentrations and are unable to compensate for light loss (Anthony and Fabricius, 2000). At even higher levels of eutrophication, gross photosynthesis and respiration, tissue thickness, and calcification start to decline in all species as light attenuation outweighs further energy gains from particle feeding. Photosynthesis, tissue thickness, and calcification therefore change in a modal fashion along eutrophication gradients (Tomascik and Sander, 1985; Marubini and Davies, 1996). In contrast, photosynthetic pigment concentrations in corals further increase with increasing eutrophication, and have, therefore, been suggested as a useful measure for eutrophication (Marubini, 1996; Cooper et al., 2009).

While corals are not directly harmed by dissolved inorganic nutrients and, within bounds, benefit from particulate organic matter, both macroalgae and heterotrophic filter feeders greatly benefit from dissolved inorganic

and particulate organic nutrients, more than corals do. Macroalgae use photosynthesis to obtain carbon and meet their nutrient demand through uptake of dissolved inorganic nutrients, plus, in some species, through demineralization of particulate organic matter deposited on their fronds (Schaffelke, 1999). In the absence of control by herbivores, some groups of macroalgae are nutrient limited and increase in growth and biomass at minute increases in dissolved inorganic nutrients and particulate organic matter (Littler and Littler, 2007). Similar to the widely observed symptoms of eutrophication in other aquatic ecosystem, macroalgae dominate coral reefs with high nutrient availability, including in areas of eutrophication (Smith et al., 1981; Lapointe et al., 2004; Lapointe and Bedford, 2007). Long-term data have shown that expanding (Cuet et al., 1988) or declining (Smith et al., 1981) macroalgal cover coincides with increasing and declining nutrient availability, respectively. These time series data indicate a causal link between macroalgal abundances and nutrient availability. On the Great Barrier Reef, total macroalgal cover increases 5-fold from highest to lowest water clarity and additionally 1.4-fold from lowest to highest chlorophyll, 3.3-fold from offshore to inshore, and 3.1-fold from northern to southern reefs (De'ath and Fabricius, 2010). Macroalgae also tend to flourish in areas of nutrient upwelling, on eastern sides of continents or large islands where more rivers originate than in the west (Birkeland, 1988), and towards higher latitudes, as do nutrient concentrations (Johannes et al., 1983). These large-scale geographic data all add evidence that nutrient levels influence macroalgal biomass. However, increases in macroalgal biomass are only observed in areas where grazing by herbivorous fishes or invertebrates is too low to control abundances (McCook, 1999; Littler and Littler, 2007) and where light levels are sufficient.

All dense macroalgal assemblages, be it low and often ephemeral mats, or taller and often perennial stands, suppress coral recruitment through space occupancy, allelopathy, silt-trapping, or shading (Connell et al., 1997; Szmant, 2002). Mat-forming macroalgae tend to also damage or kill understorey corals by restricting gas exchange and creating hypoxia when mats collapse (Loya et al., 2004). Tall perennial macroalgae, such as *Sargassum* spp., do not usually kill corals, but they can reduce coral growth by shading and tissue abrasion (Littler and Littler, 2007). As a result, corals may be outcompeted by macroalgae that grow best in high-nutrient environments – as long as light is not limiting.

Another severe consequence of eutrophication is the increased probability of outbreaks of the coral eating crown-of-thorns starfish *Acanthaster planci* (Birkeland, 1982; Brodie et al., 2005). *A. planci* has been the most prominent cause of coral mortality throughout many tropical Indo-Pacific regions in the last four decades. The pelagic planktotrophic larvae of this starfish filter-feed on large phytoplankton, and experiments suggest that these larvae are food limited: their survivorship in the

laboratory increases steeply with increasing availability of suitable food at environmentally relevant concentrations (Fabricius et al., 2010). In the field, increased nutrient availability can increase the abundance of large phytoplankton cells: a strong temporal and spatial relationship exists between drought-breaking floods from high continental islands and outbreaks of this starfish (Birkeland, 1982). New research further strengthens the evidence that more frequent outbreaks of *A. planci* are linked to high nutrient levels (Brodie et al., 2005; Houk et al., 2007). After primary *A. planci* outbreaks have formed in a region with high phytoplankton concentrations, many of their numerous larvae may be transported by currents to remote regions, hence secondary *A. planci* outbreaks may form far away from areas of eutrophication.

Benthic filter feeders, including sponges, bryozoans, bivalves, barnacles, and ascidians, are important components of reef ecosystems. Most filter feeders feed on the smallest fraction of plankton and few obtain a positive carbon balance in oligotrophic waters (Birkeland, 1988). Most benthic filter feeders live in crevices or bore holes into coral skeletons to avoid predation, and as cryptofauna they are not associated with photosynthetic endosymbionts. Fewer live on the reef surface, and these often contain photosynthetic endosymbionts, possibly accelerating growth thus enabling them to compete with hard corals and algae for space. Filter-feeder densities increase in response to nutrient enrichment, but surface-inhabiting filter feeders rarely outcompete corals for space even in eutrophic environments (Aerts and Van Soest, 1997). The few observed cases of space monopolization by a filter feeder were restricted to areas of low light, high plankton productivity, and organic enrichment (Smith et al., 1981; Brock and Smith, 1983), i.e., conditions that are unsuitable for corals. The demise of corals and the establishment of filter feeders are therefore largely independent symptoms of eutrophication, with the fate of each group determined by altered trophic conditions rather than by altered balances in space competition.

Many cryptic filter feeders are macro-bioeroders that actively bore into or chemically erode the calcium carbonate skeletons of live corals and dead reef substrata. They include boring sponges (e.g., *Cliona* spp.), bivalves (e.g., *Lithophaga* spp.), sipunculans, and polychaetes (Hutchings, 1986). Several studies have documented abundances of internal macro-bioeroders increasing in response to increased nutrient availability (Rose and Risk, 1985; Hallock, 1988; Cuet et al., 1988), and abundances of most internal macro-bioeroders are higher in productive inshore environments than they are offshore. Increased bioerosion in areas of nutrient enrichment can substantially weaken the structure of coral framework and increase storm damage. This, combined with reduced coral growth, diminished skeletal densities, and lower recruitment rates, can mean that reef erosion exceeds calcium carbonate accretion due to eutrophication (Pari et al., 2002).

### Effects of decreasing light availability due to turbidity

Benthic irradiance is an important factor determining the ability of organisms to conduct photosynthesis. At a given water depth, it is strongly governed by sediment resuspension, phytoplankton productivity, and other forms of particulate and dissolved organic matter. Sediments with large grain sizes settle near the source (e.g., in river deltas), but the smallest sediment fractions (clay and silt particles) remain suspended for days to weeks, during which times they may be transported over tens to hundreds of kilometers. Compared with larger grain sizes, these small particles absorb more light (Moody et al., 1987) and carry more nutrients and pesticides (Gibbs et al., 1971). Historic data on water clarity in marine systems are, however, sparse, and the conditions leading to long-term changes in water clarity in tropical coastal systems are poorly understood. Exceptions are records of reduced water clarity around a sewage outfall site in Kanehoe Bay, Hawaii (Hunter and Evans, 1995), and around floating fish farms in the Northern Red Sea (Loya et al., 2004).

Benthic irradiance is an essential environmental factor for corals, seagrasses, and algae. Corals can acclimatize to changing irradiance by altering their pigment density. As photoacclimation takes about 5–10 days, it is too slow to compensate for energy losses at fluctuating turbidity (Anthony and Hoegh-Guldberg, 2003). Shading from turbidity, therefore, leads to slower coral calcification and thinner tissues. Coastal coral reefs in turbid water, therefore, tend to be restricted to the upper 4–10 m compared to >40-m depths in clear oceanic waters (Yentsch et al., 2002). Reef development tends to cease at around 4–8% mean surface irradiance (Yentsch et al., 2002; Cooper et al., 2007). Coral cover and species richness decline with increasing depth at high turbidity, with the most phototrophic species being the first to disappear. Importantly, macroalgae are also missing at deeper depths despite the high availability of nutrients, as they are quickly light limited (Hillebrand, 2005). On these dark reef slopes, filter-feeder communities may be prolific. In turbid but shallow water, both light and nutrient levels are high and coral cover and coral growth rates may be very high – but only if herbivores are effective in keeping macroalgae in bay and if hydrodynamics prevent the accumulation of sediments. If herbivores are missing, the slow-growing corals tend to be outcompeted by fast-growing macroalgae.

Fishes play an essential role in the ecology of coral reefs, with low abundances of herbivorous fish potentially leading to a proliferation of macroalgae and declining coral cover (Hawkins and Roberts, 2004). Importantly, the abundance of herbivorous fish on coral reefs may potentially decline not only from overfishing, but also from nutrient pollution. Wolanski et al. (2004) reported a negative relationship between water clarity and the abundance of herbivores on the Great Barrier Reef, and a similar result was found along a water-quality gradient

in the Caribbean (Mallela et al., 2007). On the Great Barrier Reef, herbivorous fish are not usually targeted by fishers suggesting minimal fishing pressure, yet macroalgae cover extensive areas on many inshore reefs (De'ath and Fabricius, 2010), suggesting that control by herbivores is ineffective. The mechanisms for the apparent negative relationship between abundances of herbivorous fishes and poor water quality is still poorly understood; they may include an avoidance of turbidity (Wolanski et al., 2004) or a reduced food palatability, if algae trap large amounts of sediments (Mallela et al., 2007). If such negative relationship was more widespread than presently realized, then water quality would not only directly but also indirectly promote macroalgae, by releasing both nutrient limitation and grazing pressure. A systematic investigation of the potential relationships between water quality and the abundance herbivorous fishes is urgently needed.

### Effects of altered sediment properties

Coastal nutrient pollution is often linked to altered sediment properties or sedimentation regimes. Coarse sediment grains usually settle within a few kilometers of the discharge source, often contributing to forming river deltas. However, fine particles including detritus, clay, and silt particles may remain suspended for prolonged periods of time. These fine particles carry a large proportion of the total river load of nutrients and pesticides, which eventually settle onto the seafloor and onto the benthic organisms, sometimes tens to hundreds of kilometers away from the source.

Previous studies have mostly focused on assessing the effects of increased rates of sedimentation on coral reefs. Sedimentation rate is a strong environmental driver for coral reefs. It is known to reduce coral recruitment rates and coral biodiversity, and many sensitive species are missing or underrepresented in areas of high sedimentation (Rogers, 1990; Fabricius, 2005). Photophysiological stress in corals increases linearly as the product of the duration and amount of sediment exposure, i.e., two units of sediment deposited on the coral for one time unit, exerts a similar decline in photosynthetic yields as half the amount deposited for twice the time (Philipp and Fabricius, 2003). High sedimentation rates (up to 100 mg dry weight  $\text{cm}^{-2}$ ) can kill exposed coral tissue within a few days. Exposure to a few days of sedimentation can therefore cause long-term damage to coral populations, by removing whole cohorts of small and sensitive corals. Previous studies have suggested a sedimentation threshold of 10 mg  $\text{cm}^{-2} \text{ day}^{-1}$ , as reefs may be severely damaged at higher rates (Rogers, 1990).

Eutrophication may, however, not always increase the rate of sedimentation, but may alter sediment properties. Experiments have shown that when coral tissue is exposed to sedimentation, the degree of damage increases with bacterial activity (Hodgson, 1990) and with decreasing grain sediment sizes (Weber et al., 2006). Nutrient-rich sediments and sediments with high organic contents cause

greater stress and damage to corals than do sediments that are poor in organic matter (Weber et al., 2006). Fine and organically enriched sediments may support different bacterial communities and metabolic processes, further altering the microenvironment on the reefs biofilm surfaces. Fine sediments may also bind with marine snow aggregates, and this additional organic material is highly damaging to coral recruits (Fabricius et al., 2003). At very high levels of pollution, the decomposition of organically enriched sediments can lead to hypoxia in poorly flushed and highly stratified locations, further damaging benthos. Not only the amount of sedimentation and its geochemical and physical properties, but also its biological properties and organic contents are ecologically relevant and determine the extent of sedimentation damage in coral reefs.

Corals are most sensitive to sedimentation during their recruitment stage, and reduced coral recruitment is one of the most deleterious effects of eutrophication on coral reefs. Coral settlement is sparse on sediment-covered surfaces, and the tolerance of coral recruits to sediment is at least one order of magnitude lower than that of adult corals (Fabricius, 2005). Newly settled corals may be killed by exposure to  $12 \text{ mg cm}^{-2} \text{ day}^{-1}$  for  $<48 \text{ h}$  if the sediment is bound by marine snow and rich in organic contents, but can tolerate such levels if the sediments are low in organic content (Fabricius et al., 2003). These and similar data demonstrate the critical role of organic sediment enrichment and the interactions of nutrients and sediments on the effects on coral reefs.

Certain species of crustose coralline red algae are essential for coral settlement. While high nutrient levels do not greatly alter the physiology of crustose coralline algae, high sedimentation rates are related to low coralline algal cover in coral reefs (Kendrick, 1991; Fabricius and De'ath, 2001). Some coralline red algae survive burial under coarse inorganic sediments for days to weeks, but their survival rates rapidly decline if the sediments contain traces of herbicides (Harrington et al., 2005). Turf algae often outcompete coralline algae, and by trapping sediments they can make the substratum unsuitable for coralline algae and for coral settlement (Birrell et al., 2005).

### Factors determining the vulnerability of a specific coral reef to eutrophication

Effective coastal management requires an understanding of the factors that determine the vulnerability of specific coral reefs to eutrophication. Vulnerability may vary depending on the reef's exposure, resistance, and resilience.

The degree of exposure of an organism or ecosystem to a stressor is typically a function of the amount (= concentration, level, or load) of the stressor and the length of time it is in contact with the stressor. A reef may be exposed to a high level of a stressor for a short period of time or to lower levels for longer periods. When quantifying exposure levels, it is important to determine peak concentrations (potentially leading to damage or mortality within

hours to days), as well as to quantify long-term mean (or median) concentrations and the duration of exposure.

The resistance of an ecosystem is defined as the ease or difficulty with which it changes when exposed to a disturbance (Pimm, 1984). Resistance can arise from prior exposure history, environmental factors, or biological factors (Done, 1999; West and Salm, 2003). For example, a coral reef that has developed in a naturally turbid setting and is dominated by corals of the turbidity-tolerant genera *Turbinaria* and massive *Porites* is more resistant to change from exposure to nutrient pollution than an *Acropora*-dominated reef that has developed in clear waters. Ecological resilience is defined here as the time it takes for an ecosystem to return to its equilibrium point after being disturbed (Nyström et al., 2008).

A review of some of the better-described case studies in the literature allows to qualitatively identify the main factors that predict the exposure, resistance, and resilience of specific reefs to degradation. Currents are extremely important properties of coral reefs and are key predictors of exposure, resistance, and resilience at both local and regional scales. At local scales, current-swept reef fronts, flanks and channels, and reef crests with moderate wave exposure are the least likely to retain pollutants; they support high recruitment and have the fastest coral growth (Sebens, 1991). Ideally, wave exposure is sufficient to remove sediment deposits without causing frequent coral breakage. As fast currents and waves also facilitate macroalgal growth, competition between corals and macroalgae is intense if nutrient levels are high. At regional scales, currents determine where and how far pollutants are being transported. Where currents are predominantly tidal, a very low or very high tidal range diminishes the ability of reefs to withstand pollution, by affecting circulation. Currents that create a strong connectivity to source populations of pelagic larvae also improve the resilience of a reef, by decreasing the time of recovery from a disturbance.

The exposure of a coral reef is furthermore well predicted simply based on spatial factors: the closer downstream a coral reef is to a pollution source and the higher the mean annual load of this source, the greater is its exposure to a pollutant (Bryant et al., 1998). Geospatial models of the global scale of pollution around coral reefs have been developed based on the distance of reefs to pollution sources (Bryant et al., 1998). These models estimate that 22% of all coral reefs worldwide are classified as at high or medium threat from inland pollution and soil erosion. The global models also classify 12% of reefs at threat from marine pollution (distance from ports, oil tanks, oil wells, and shipping areas) and 30% of reefs as threatened from coastal development such as cities, mines, and resorts (Bryant et al., 1998). At regional scales, the percentage of reefs at risk is a direct function of the extent of land clearing, and up to 50% of reefs is at risk in the countries with the most widespread land clearing (Bryant et al., 1998). At local scales, such as downstream from well-defined point sources

or in coastal reefs fringing eroding land, terrestrial runoff can be the single most significant pressure for selected coral reefs (Bourke et al., 2002). However, such geospatial models do not factor in additional indirect effects that may occur hundreds of kilometers away from areas of eutrophication, such as increasing frequencies of outbreaks of coral eating crown-of-thorns starfish populations.

Topography/geomorphology and bathymetry can modify exposure enormously: pollutants are retained for prolonged periods in poorly flushed embayments and lagoons with reduced circulation or small water volumes, whereas they may be rapidly washed away from a headland surrounded by a deep water body (Hopley et al., 2007). Around the world, most severely polluted and hypoxic marine sites are located in shallow and poorly flushed semienclosed waterbodies such as gulfs, bays, fjords, or bights (e.g., Kaneohe Bay, the Baltic Sea, Chesapeake Bay, Irish Sea; Diaz, 2001). Bathymetry also modifies exposure by affecting the balance between sedimentation and resuspension of materials. Materials are easily washed away from shallow, upper reef slopes, but accumulate below the reach of surface waves in deeper areas (Wolanski et al., 2005). Upper reef slopes are also less affected by turbidity than are deeper areas, where light becomes limiting for photosynthetic organisms. Exposure is worst at sites surrounded by a wide, shallow continental shelf where materials are repeatedly wave resuspended, whereas pollutants are flushed away into deeper waters if no shelf retains them. For example, the Great Barrier Reef is located on a 50–200-km-wide shallow continental shelf with >2,000 individual coral reefs between the land and the open ocean. Retention times here are still being debated, but some estimate them to be up to 300 days for dissolved materials (Luick et al., 2007). Particulate materials are likely to be retained for even longer periods of time, as they are repeatedly deposited and resuspended from the shallow sea floor. So, although nutrient enrichment is less severe on the Great Barrier Reef than in many other more densely populated regions, symptoms such as macroalgal dominance and low coral diversity on numerous inshore reefs have been attributed to enhanced terrestrial runoff (van Woesik et al., 1999; Fabricius and De'ath, 2004; Fabricius et al., 2005; De'ath and Fabricius, 2010).

Lastly, biological processes are believed to modify the resistance and resilience of coral reefs, but many of these processes are as yet poorly understood. For example, abundant herbivorous fish strongly control macroalgal abundances, thereby promoting resilience (Littler and Littler, 2007). It is also still unresolved to what extent resistance and resilience are codetermined by biodiversity; biogeographic regions with low biodiversity have fewer species to replace the loss of sensitive species and may be more likely to undergo structural and functional changes in their communities (Bellwood et al., 2004). For example in the Caribbean, the loss of the dominant coral species *Acropora palmata* and *Acropora cervicornis* and the one remaining important algal grazer, *Diadema antillarum*, has led to a widespread collapse of reef

ecosystems (Lessios et al., 1984). It is also unknown whether or not the resistance and resilience of reefs vary along latitudinal gradients, as reefs in higher latitudes naturally have lower calcification rates, higher macroalgal biomass, and lower coral biodiversity than do low latitude reefs. Lastly, regions that are prone to severe or frequent disturbances (e.g., from coral bleaching, storms, cold water upwelling, or outbreaks of *A. planci*) are more likely to be prone to degradation than rarely disturbed regions. This is because poor water quality often does not directly kill the adult coral populations, but retards coral recruitment and hence the speed of recovery from unrelated disturbances. It has also been shown that exposure to one form of stress may decrease the resilience of an ecosystem to another stressor (Hughes et al., 2003; Wooldridge et al., 2005).

In summary, degradation from poor water quality is most likely to occur on deeper reef slopes, in locations with weak currents, in places where fish abundances are low, and in regions that are frequently affected by other forms of disturbance. In contrast, well-flushed locations with strong currents, shallow reef crests surrounded by a deep water body, and reefs inhabited by healthy populations of fishes are likely to have the highest levels of resistance and resilience.

Several of these factors are identical to those that determine the resistance and resilience of coral to bleaching caused by warming oceans. For example, topography, fast currents, proximity to deep water, and a diverse community with abundant herbivores are considered reliable factors in predicting the likelihood of coral communities dying as a result of bleaching (West and Salm, 2003) – as they are in predicting death arising from eutrophication. One difference is that reefs in shallow waters are – relative to deeper reef slopes – tolerant of the turbidity associated with eutrophication but sensitive to bleaching. A better understanding of the additive or interactive effects between eutrophication and climate change is clearly needed.

## Conclusions

Although disturbances are a normal and important aspect of their environment, coral reefs are inherently quite stable over time, with coral cover and composition often not changing for many years to decades (Connell, 1997). After severe acute and short-term disturbances, coral in shallow, well-lit windward reefs with fast currents can recover within 10–15 years, if larvae are plentiful (Connell, 1997). Recovery takes longer – possibly up to 50 years – on deeper reef slopes and in poorly flushed settings such as lagoons and areas with weak water flow and poor connectivity. Recovery from chronic and human-induced disturbances that alter the physical environment is also slower and less commonly observed than recovery from fast and acute disturbances (Connell et al., 1997). If widespread reef degradation is to be avoided, it is essential that the average frequency of severe disturbances does not

exceed the average recovery time in any one location and that chronic disturbances are minimized. In recent times, the frequency and nature of major disturbances, such as coral bleaching, outbreaks of *A. planci*, and severe storms, have exceeded the capacity of many reefs around the world to recover (Wilkinson, 2004). Such large-scale events are typically not controllable by management action. In contrast, eutrophication is much more manageable and can often be prevented by preservation of vegetation cover on land, reduction of fertilizer loss into the sea, and restriction of aquaculture facilities to well-flushed locations where dilution is rapid and the resistance and resilience of the marine ecosystems are greatest. With increasing reef disturbances as a result of global warming and seawater acidification, management of water quality and healthy fish abundances will be critically important to the future of coral reef ecosystems.

## OCEAN ACIDIFICATION, EFFECTS ON CALCIFICATION

Joan A. Kleypas  
National Center for Atmospheric Research, Boulder,  
CO, USA

### Synonyms

Lowered pH of seawater

### Definition

*Aragonite*: A calcium carbonate ( $\text{CaCO}_3$ ) mineral with an orthorhombic crystal lattice structure; a polymorph of calcite.

*Calcification*: The process by which an organism secretes calcium carbonate.

*Calcite*. A calcium carbonate ( $\text{CaCO}_3$ ) mineral with a trigonal (rhombohedral) crystal lattice structure; a polymorph of aragonite.

*High-Mg calcite*: Calcite containing at least 4 mol%  $\text{MgCO}_3$ .

*Ocean acidification*: The decrease in the pH of the Earth's oceans caused by the uptake of carbon dioxide from the atmosphere.

*Rhodoliths*: Coralline algae that grow in rounded, free-living forms that are unattached to the substrate.

*Saturation state*: A measure of the thermodynamic potential of a mineral to precipitate or dissolve.

### Introduction

Technically, the term “ocean acidification” refers to any process that causes a decrease in seawater pH. Today, however, the term refers almost exclusively to the process by which oceanic water absorbs carbon dioxide from the atmosphere, causing a decrease in ocean pH and changes

in other chemical properties of seawater. Ocean acidification is not a consequence of climate change, but the two share a common cause: increasing concentration of carbon dioxide in the atmosphere. Ocean acidification can affect coral reefs in multiple ways: effects on biogeochemical processes, physiology of organisms, and even such things as sound transmission, have been demonstrated. However the best-documented effects are those on organisms that secrete calcium carbonate, most notably corals, coralline algae, and foraminifera, which are major contributors to reef growth.

### Chemistry of ocean acidification

The chemical reactions involved in ocean acidification are well documented, albeit somewhat complicated. Carbon dioxide reacts with seawater to form carbonic acid:

Most of the carbonic acid dissociates quickly to hydrogen ions (a contributor to acidity) and bicarbonate ions:

and some of the bicarbonate also dissociate to hydrogen ions and carbonate ions:

When carbon dioxide is added to seawater, the relative proportions of the carbonic acid complex (dissolved  $\text{CO}_2$  and  $\text{H}_2\text{CO}_3$ ), bicarbonate, and carbonate, shift to maintain charge balance in seawater. This comprises the buffering capacity of seawater to maintain pH. For example, the addition of carbon dioxide to seawater causes an increase in bicarbonate ion concentration, a decrease in carbonate ion concentration, and a decrease in pH. The following

further illustrates the reaction of carbon dioxide and water in the presence of calcium carbonate ( $\text{CaCO}_3$ ) minerals:

Calcium carbonate production thus releases  $\text{CO}_2$  to the water column while its dissolution removes  $\text{CO}_2$ .

The calcium carbonate saturation state ( $\Omega$ ) is a measure of the ion activity product of  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  relative to the apparent solubility product ( $K'$ ) for a particular calcium carbonate mineral (e.g., calcite or aragonite). The surface ocean is supersaturated ( $>1$ ) nearly everywhere (Figure 1), but spontaneous precipitation of carbonate minerals is constrained by kinetic barriers. Calcium is much more abundant than carbonate in seawater, so changes in

$\Omega$  mostly reflect changes in the carbonate ion concentration. The calculated  $\Omega_{\text{aragonite}}$  for the tropical oceans, based on a combination of measurements taken in the 1990s (GLODAP, World Ocean Atlas), ranged between about 3.2 and 4.5 (Figure 1a). Most of this variation is due to the 18–30°C temperature range. First order calculations that take into account the progressive increase in atmospheric  $\text{CO}_2$  concentration (with an associated temperature increase) show that aragonite saturation state will decrease to levels outside the preindustrial range (Figure 1b).

### Effects on formation and dissolution of calcium carbonate

Calcium carbonate production in the oceans is almost entirely biogenic, and most is precipitated as one of two

**Ocean Acidification, Effects on Calcification, Figure 1** (a) Aragonite saturation state of tropical oceans estimated by combining  $1 \times 1^\circ$  gridded fields of total alkalinity and total dissolved inorganic carbon normalized to 1990 conditions (GLODAP data base, Sabine et al., 2005) with  $1 \times 1^\circ$  gridded fields of average annual temperature, salinity, phosphate, and silicate (World Ocean Database, 2005; Boyer et al., 2006). Note that these values are highly interpolated and should not be used for research purposes. (b) Aragonite saturation state as a function of atmospheric  $\text{CO}_2$  concentration. Lower and upper solid lines are calculated for 18 and 30°C seawater, respectively, with total alkalinity of  $2,300 \mu\text{eq kg}^{-1}$ , and negligible phosphate and silicate. Parallel dashed lines indicate general range of aragonite saturation state in reef areas prior to the Industrial Revolution. Vertical lines show range of aragonite saturation states at preindustrial atmospheric  $\text{CO}_2$  concentration (280 ppm), the present decade (390 ppm), and 2x preindustrial (560 ppm).

polymorph minerals: calcite, which has a rhombohedral crystal structure; and aragonite, which is orthorhombic. The calcite crystal structure allows some substitution of magnesium ions (Mg) for calcium ions, and calcite with >4 mol%  $\text{MgCO}_3$  is called “high-Mg calcite.” Normally, calcite is much less soluble in seawater than aragonite, but high-Mg calcite with 12–16 mol%  $\text{MgCO}_3$  is about 20% more soluble than aragonite (Morse et al., 2006). Many other factors (impurities, structural disorder) can equally affect the solubilities of calcite, high-Mg calcite, and aragonite.

The saturation states of the various minerals affect the rates of crystallization and dissolution. The rate of calcium carbonate formation, for example, is often expressed as the equation:  $R = k(\Omega - 1)^n$ , where  $k$  is the rate constant and  $n$  the reaction order.

The solubilities of the calcium carbonate minerals have been of interest to Earth scientists for some time, mainly because interpreting Earth’s history requires an understanding of the processes controlling production and preservation of calcium carbonate deposits. Waters of low pH, such as those in the deep sea, have long been known to be corrosive to calcium carbonates, as first noted by Murray and Renard (1891).

Marine calcifying organisms typically precipitate either one mineral or the other, and only a few species have the capacity to precipitate two. In general, calcite secretors (e.g., coccolithophorids) occur in higher latitudes where colder waters can hold more  $\text{CO}_2$  and thus have lower carbonate saturation. Organisms that precipitate the more soluble minerals aragonite (e.g., scleractinian corals) and high-Mg calcite (e.g., crustose coralline algae) are favored in low latitudes, which have higher saturation. Over geologic time, the dominant mineralogy of shallow water carbonates, as well as their preservation potential, has also fluctuated with shifts in seawater carbonate chemistry (Sandberg, 1983). The preferential disappearance of corals and other marine reef-builders in several major extinction events is coincident with rapid ocean acidification (Veron, 2008; Knoll et al., 2007).

### Effects on calcification of marine organisms

Controlled laboratory experiments have provided most of the evidence that ocean acidification will reduce calcification in corals and coralline algae. Results of these experiments indicate that calcification rates of most tropical coral species will decline significantly as ocean acidification proceeds (reviewed in Kleypas and Langdon, 2006; Langdon and Atkinson, 2005). A wide range of responses has been observed, but on average, experimental results under conditions of  $2\times$  preindustrial  $\text{CO}_2$  concentrations fall within two response classes: (1) >40% reduction in calcification rate and (2) <10% reduction (Langdon and Atkinson, 2005). Calcification in newly settled coral polyps may also be impaired at elevated  $\text{CO}_2$  (Albright et al., 2008). There is no evidence yet that corals can adapt to these changes, but the response is reversible

(calcification will increase if pH is increased). The skeletons of some live coral species dissolve completely when placed in waters undersaturated with respect to aragonite, with the coral polyps left in a “naked” or anemone-like state (Fine and Tchernov, 2007). These can re-precipitate skeletons when replaced in waters of normal aragonite saturation. The coral polyps appeared unharmed in these experiments, but naked corals are considered vulnerable in the wild, and would lose their reef-building function.

Experimental results indicate that calcification rates of tropical reef-building coralline algae and rhodoliths respond more strongly to ocean acidification than those of corals, which may be due in part to the high-Mg calcite mineralogy of coralline algae skeletons. Some experiments show net dissolution of coralline algae at atmospheric  $\text{CO}_2$  concentrations as low as 700 ppm (Kuffner et al., 2008; Jokiel et al., 2008; Anthony et al., 2008). The recruitment of tropical crustose coralline algae in experimental mesocosms is also reduced at higher  $\text{CO}_2$  concentrations (Kuffner et al., 2008).

Evidence that ocean acidification is currently affecting reef-building organisms has been difficult to obtain, mainly because of the difficulty in measuring calcification rates over time. Calcification rates derived from coral skeletons of massive *Porites* species indicate a dramatic decrease in calcification beginning around the year 1990 (De’ath et al., 2009), but it is unclear whether this decrease is due to increased temperature, ocean acidification, or a combination of the two.

The effects of decreased calcification on the survival of calcifying reef organisms are not well understood. Some calcifying organisms become absent near a natural submarine  $\text{CO}_2$  vent in a shallow region of the Mediterranean (Hall-Spencer et al., 2008). Calcium carbonate shells and skeletons probably have a protective function, but may also allow organisms to secure themselves to the substrate, compete for space, or optimize light gathering for photosynthesis.

### Effects on coral reef structures

Coral reef structures are produced by the accumulation of  $\text{CaCO}_3$  skeletal debris of corals, coralline algae, and other reef calcifiers. Ocean acidification slows net calcium carbonate production by decreasing carbonate production and/or increasing carbonate dissolution (Kleypas et al., 2001). Dissolution rates of reef sediments increase significantly under elevated  $\text{CO}_2$  conditions, particularly in sediments with a high percentage of high-Mg calcite (Yates and Halley, 2006; Andersson et al., 2007). Monitoring of net community calcification rates on coral reefs (Silverman et al., 2009a) indicate that many or most coral reefs will shift to a state of net dissolution once  $\text{CO}_2$  concentration reaches  $2\times$  preindustrial levels (Silverman et al., 2009b). Other studies suggest that, under elevated  $\text{CO}_2$  conditions, inorganic cementation of coral reef structures is lower, and erosion rates are higher (Manzello et al., 2008). Erosion rates of common microscopic euendolithic

algae that bore into coral skeletons have also been shown to increase dramatically under elevated CO<sub>2</sub> conditions (Tribollet et al., 2009). Decreased calcium carbonate production and increased erosion is likely to reduce architectural complexity of a reef (Alvarez-Filip et al., 2009), and thus may affect reef biodiversity.

### Other effects of ocean acidification on coral reefs

Ocean acidification causes a suite of changes in the carbonate system in seawater, and some of those changes affect other physiological processes in reef organisms. Some corals and coralline algae have been shown to bleach at lower temperature thresholds under lowered pH conditions (Anthony et al., 2008). The olfactory senses of larval orange clownfish *Amphiprion percula* were impaired under lowered pH conditions, which affected their homing ability (Munday et al., 2009). Some organisms, however, may benefit from ocean acidification. Seagrasses, for example, have been shown to increase growth rates from CO<sub>2</sub>-fertilization (Palacios and Zimmerman, 2007).

### Summary

Ocean acidification, a consequence of the ocean's increased absorption of CO<sub>2</sub> from the atmosphere, causes shifts in multiple components of the carbonate system in seawater. One of the best-known impacts of ocean acidification on coral reefs is the reduced rate of calcification in corals and coralline algae. Calcification rates of both groups are expected to decrease significantly with further increases in atmospheric CO<sub>2</sub> concentrations, and dissolution of reef rock and sediments will increase. The direct effects of ocean acidification on organism survival and ecosystem functioning are not well known, but loss of reef habitat and architectural complexity are expected outcomes. Findings from multiple fields of study (paleontology, paleoecology, chemical oceanography, biochemistry, isotope geochemistry, etc.) suggest that ocean acidification will lead to decreased calcium carbonate production, a shift from reef-building toward reef destruction, and reduced biodiversity of reef ecosystems.

## OCEANIC HOTSPOTS

Paul Wessel  
 University of Hawaii at Manoa, Honolulu, HI, USA

### Definition

Site occupied by a seamount or oceanic island, usually located away from plate boundaries, where long-lived (>5 Myr), volcanism occurs or has recently occurred.

### Introduction

Volcanism occurs mainly at or near active plate boundaries, in particular at mid-ocean ridges. However, there are important exceptions where volcanic activity occurs within plate interiors. In the ocean basins, the prime observational evidence comes from the presence of linear chains of islands and seamounts, sometimes extending for thousands of kilometers across the ocean basins. These island and seamount chains exhibit a general progression of decreasing elevation along the chain from volcanic island to fringing reef, to atoll, and finally to a submerged flat-topped seamount (guyot). An active or dormant volcano usually occupies the young end of an island chain, with progressively older and extinct volcanoes occurring along the rest of the chain. Such topographic features were

suggested to have formed as the plate moved over a relatively stationary “hot spot” in the Earth’s mantle, where an upwelling mantle plume brings hot magma from great depths to the surface (Morgan, 1971; Wilson, 1963). The archetypal example of this process is the Hawaiian-Emperor seamount chain (Figure 1). The mantle plume that produced this ~6,000 km long chain is presently situated beneath the Big Island of Hawaii, the site of active volcanism today. Extending 3,500 km to the northwest lies a linear chain of islands, atolls, and seamounts; there, near the Diakakuji Seamount the chain exhibits a sharp ~60° change in orientation and continues another 2,500 km north-northwest to the Aleutian trench. The age of the volcanism gets progressively older with increasing distance from Hawaii, which is seen as a key observation that validates the hot spot hypothesis. Although predominantly an oceanic phenomenon, hot spot volcanism is not restricted to the ocean basins; volcanism of a similar type occurs within continents, one example being the activity of Yellowstone National Park in the western North America.

### Origin of oceanic hotspots

The hotspot hypothesis states that seamount chains and oceanic islands are the surface manifestation of impinging mantle plumes. These upwelling mantle plumes are thought to originate either at the core-mantle boundary (2,900 km depth) or the boundary between the lower and upper mantle (670 km depth). One theory suggests that a “plume head” develops, above a “plume stem” (e.g., Richards et al., 1989) but other scenarios of plume development with double plume heads (Bercovici and Mahoney, 1994) and time varying magma output (Coffin et al., 2002) have also been considered. As originally proposed (Morgan, 1971; Wilson, 1963), these plumes were considered stationary relative to the lithospheric plates that move over them, but recent evidence suggests that some plumes may have experienced considerable drift over their active lifespan. In particular, deep-sea drilling of seamounts in the northern Emperor seamount chain recovered oriented samples the magnetic memories of which imply that they must have formed at latitudes some 10–15° further north than the present location of the Hawaii hot spot. These systematic discrepancies have led to suggestions that the mantle plume was further north in the past and consequently has drifted south since the formation of these seamounts (e.g., Tarduno et al., 2009).

It is not entirely clear how mantle plumes manage to reach the surface. Apparently weakened by the impinging plume, the lithosphere allows magma to migrate through cracks and fractures and eventually reach the surface. There, a volcano builds upon the surface of the plate directly above the plume. The constant motion of the plate, however, will eventually carry the volcano too far from the source of magma and the volcano becomes extinct. As extinct volcanoes no longer have the

**Oceanic Hotspots, Figure 1** Geometry and ages of the Hawaii-Emperor seamount chain. The major bend in the chain occurred at 47–50 Ma (Sharp and Clague, 2006). Hotspot location (star) is located near Kilauea. Triangles indicate position of samples and their radiometric age is indicated by the color. White arrow shows the approximate Pacific absolute plate motion since ~47 Ma.

regenerative volcanism to combat erosion, they subsequently erode as they cool and subside to form fringing reefs and atolls. With time, they eventually sink below the surface of the sea to form a seamount. Wave action will often flatten the top of such seamounts, leading to the classical truncated guyot (Hess, 1946). As long as the mantle plume supplies heat and magma, new active volcanoes will form directly above the mantle plume and the process continues. Mantle plumes may stay active from a few tens to a few hundred million years.

The relative motion between plates and plumes causes the formation of lines of extinct volcanoes; these exhibit monotonic age progressions and reflect the history of past plate motions. Since the early formulation of the hotspot hypothesis, numerous hotspots have been proposed for sites of unusual volcanic activity (e.g., Burke and Wilson, 1976; Clouard and Bonneville, 2001; Sleep, 1990) yet conclusive imaging of the underlying mantle plumes using seismic tomography remains elusive (Nataf, 2000), perhaps with Iceland (Wolfe et al., 1997) as an exception. For instance, the archetypal strong plume that many believe has formed the Hawaii-Emperor seamount chain and currently thought to underlie the southeast end of the Big Island of Hawaii is not well resolved, whereas other, less productive hotspots (e.g., Easter, Ascension, Azores) appear more dominant in the tomographic images (Montelli et al., 2004). However, recent three-dimensional seismic imaging beneath the Hawaiian Islands now seem to require an upwelling mantle plume (Wolfe et al., 2009). Although the simple age progressions predicted by the hotspot hypothesis are borne out by observations for several seamount chains (such as the Hawaii-Emperor and Louisville chains), others exhibit a more complex age pattern which casts some doubt on the hotspot theory being the only explanation for such volcanism (e.g., McNutt et al., 1997).

### Mantle plumes and hotspot swells

Large bathymetric swells may form around and downstream from the site of active hotspots (e.g., McNutt, 1998). While seamount chains are usually confined within a relatively narrow zone (~100–200 km), the broader effect of plumes on the lithosphere and upper mantle can extend for ~1,000 km or more. Again, the most well-known case of a hotspot swell is associated with the Hawaiian chain where the seamounts are centrally arranged on top of a broad (~1,200 km) swell extending for ~3,000 km (e.g., Van Ark and Lin, 2004). Despite this classic example, similar thermal swells are found in all oceans and always associated with hotspot chains. The amplitude and extent of such swells correlate strongly with the age of the underlying lithosphere; hence Hawaii (located in an area with seafloor of around 100 Ma) is more elevated than similar swells found in French Polynesia where the seafloor is only half that age (Cazenave et al., 1988). The earliest studies of hotspot swells concluded that the shallow bathymetry simply reflected reheating of the entire lithosphere (Detrick and Crough, 1978). However, others have pointed out the likely effect of compositional buoyancy (e.g., Jordan, 1979; Phipps Morgan et al., 1995) and dynamical uplift (e.g., Olson, 1990). In summary, hotspot swells appear to require the presence of a deep-seated upwelling plume as such features can explain both a broad swell and narrowly focused volcanism (e.g., Ribe and Christensen, 1999).

### Intraplate seamounts produced at oceanic hotspots

Seamounts formed by hotspot volcanism can accumulate into the largest seamounts present in the oceans. Specifically, intraplate seamounts built on old (and hence thick

and strong) oceanic lithosphere may in some circumstances attain heights of almost 10 km (measured from the seafloor to the tallest peak on an island). This is the case for Mauna Kea, one of five volcanoes that form the Big Island of Hawaii, which by this definition is the tallest mountain on Earth. Given that the smallest features considered by most geologists to be seamounts are 50–100 m tall, the sizes of observed seamounts span almost three orders of magnitude.

Studies have found that the number of seamounts varies considerably across the oceans and that they tend to form both linear and random constellations. Furthermore, their sizes and distributions provide invaluable information about their origins. Ranging from single-beam echosounder profiles, via multibeam surveys, to satellite altimetry, studies have found that the distribution of seamounts can be reasonably well explained by an exponential or power-law model (e.g., Craig and Sandwell, 1988; Smith and Jordan, 1987; Wessel, 2001). Such models support the observation that most seamounts are fairly small. Extrapolations from the power-law trends obtained for large seamounts suggest that perhaps over 100,000 seamounts of heights  $\geq 1$  km may be present in the oceans. Extrapolating further down to the smallest sizes observed (a few tens of meters) would predict a population over one million. However, sediments will most likely have buried the bulk of those seamounts, considering typical 100–200 m sediment thicknesses in the ocean basins (e.g., Ludwig and Houtz, 1979). Consequently, we find that most of the smallest seamounts reside on young seafloor where the sediment cover is modest or nonexistent.

We do not know why seamount abundances vary spatially. One factor may be the underlying distribution of mantle plumes, which seem to be found in higher numbers beneath plates with the largest seamount abundances. Another factor may be systematic variations in plate stresses. We note that smaller plates are possibly in compression, which could prevent the intrusion of magma. Smaller plates are also less likely to have a directional regional stress dominating the state of stress, and often are relatively young and buoyant (e.g., the Cocos plate); during subduction, such plates would only be associated with slightly negative buoyancy forces. On the other hand, the large Pacific plate, and specifically its equatorial region, appears to be under tension from the slab pull forces at the distant subduction zones, as evidenced by widespread extensional volcanism that is neither associated with hotspots nor mid-ocean ridges (e.g., Sandwell et al., 1995; Wessel and Kroenke, 2007). Finally, plates that move the fastest over the underlying mantle appear to have the highest seamount abundances provided they share at least one spreading plate boundary.

## Summary

Oceanic hotspots are the surface expression of rising mantle plumes from the Earth's interior and are responsible for much of the intraplate volcanism observed in the ocean

basins. Being relatively stationary with respect to the surrounding mantle, the oceanic hotspots produce linear chains of islands and seamounts as tectonic plates move over these sites.

## OCTOCORALLIA

Katharina Fabricius  
 Australian Institute of Marine Science, Townsville,  
 QLD, Australia

## Synonyms

Alcyonaria (this term is now rarely used). Common names: Gorgonians; Octocorals; Sea fans; Sea pens; Sea whips; Soft corals

## Definition

Octocorallia (also known as octocorals, or in earlier times “Alcyonaria”) are a subclass of the class Anthozoa, in the phylum Cnidaria. They are sessile polyp-bearing animals with a mobile larval phase that are only found in marine systems. The distinguishing characteristic of this subclass is that their polyps always bear eight tentacles (hence octocoral), which are usually (but not always) fringed along both edges by one or more rows of pinnules. The gastro-vascular cavities are typically subdivided by eight septa.

## Introduction

Octocorals are a major component of the sessile benthic fauna of many coral reefs. Like Scleractinian corals, they are modular (colonial) organisms which develop through asexual replication and specialization of polyps. In contrast to Scleractinian corals (the primary reef building corals), most octocorals do not usually deposit a rigid calcium carbonate exoskeleton, and they therefore tend to attach to reefs rather than contribute substantially to their framework or to sedimentary deposits. However, there are a number of exceptions that do contribute substantially to framework accretion, sedimentary deposits, and sediment stabilization (see below).

## Classification

Octocorallia are a subclass of the class Anthozoa, phylum Cnidaria. Like other anthozoans, octocorals bear polyps that consist of a tubular body, terminating in a mouth that is surrounded by hollow tentacles. Unlike other anthozoans, octocoral polyps always bear eight tentacles, which are usually fringed by rows of pinnules. Polyps are internally compartmentalized by eight mesenteries. The ectoderm of the tentacles contains simple nematocysts (cnidae or stinging cells) that are unable to paralyze large zooplankton or sting other larger animals. The ectodermal and endodermal cell layers are often connected by a relatively thick and cellular mesoglea, which often contains calcium carbonate sclerites and collagen. Most octocorals are colonial, with the exception of one deep-water species with a single solitary polyp (*Taiaroa tauhou*). A colony develops from a single founder polyp by asexual propagation (polyp budding). The resulting multiple polyps in a colony are often embedded into coenenchymal tissue, but remain connected by canals (solenia).

There is substantial taxonomic uncertainty associated with Octocorallia. At present, the subclass is divided into three orders ([Figure 1](#)):

- Helioporacea
- Pennatulacea (sea pens)
- Alcyonacea (soft corals and gorgonians)

The Helioporacea are represented by a single species, the blue coral, *Heliopora coerulea* (family Helioporidae) in the Indo-Pacific, and the genus *Epiphaxum* (family Lithotelestidae) in the Caribbean. *H. coerulea* has no calcium carbonate sclerites, instead colonies consist of a massive aragonite skeleton perforated by wide cylindrical cavities containing the polyps, connected by narrow solenial tubes.

The Pennatulacea (sea pens) presently distinguish around 200 species in 32 genera (15 families; Williams, 1995, 1999). The body of pennatulaceans consists of a single large primary polyp, called the oozoid, with a basal fleshy peduncle for anchorage in soft substratum. Through lateral budding of the upper body wall of the oozoid (rachis), two types of secondary polyps are being

**Octocorallia, Figure 1** Representatives of the three orders of Octocorallia: (a) Helioporacea; (b) Pennatulacea; (c and d) two common morphological groups of Alcyonacea, soft corals, and gorgonians.

formed, autozooids and siphonozooids, with mesozooids as an additional third type of polyps in a few taxa. Pennatulaceans typically live in soft bottom habitats, being completely retracted during the day and emerging in the dark. The greatest pennatulacean diversity is found in the tropical Indo-Pacific (nine genera in five families).

The Alcyonacea (soft corals and gorgonians) contain the large majority of octocoral species. The number of species is unknown, as numerous species await taxonomic

description and many genera need urgent revision. In shallow tropical and subtropical Indo-Pacific reefs alone, about 100 alcyonacean genera in 23 families are currently described (Fabricius and Alderslade, 2001). Their growth forms range from small colonies with few polyps connected by stolons, to fleshy soft corals to up to 3 m large sea fans (Figure 2). Within the order Alcyonacea, the term “soft coral” is commonly used to only refer to octocorals without internal axis or solid skeleton. In

**Octocorallia, Figure 2** Representative morphological groups of alcyonacean octocorals: (a) single polyps connected by stolons; (b) tall axial polyps that bud off lateral polyps; (c) polyps embedded in a fleshy tissue mass ("soft coral"); (d) gorgonian sea fan with upright growth form and internal axis (modified from Hyman, 1940).

**Octocorallia, Figure 3** A representative set of octocoral sclerites of the genus *Acanthogorgia*. Sclerites are the main feature used for taxonomic analyses (drawing by P. Alderslade, from Fabricius and Alderslade, 2001).

contrast, the terms gorgonian, sea fan, sea rod, or sea whip are generally used to refer to octocorals that arise from the substratum with the support of an internal axis (but excluding sea pens and blue coral). However, in the Caribbean where gorgonians dominate the octocoral fauna, the term soft coral is often used for all octocorals. While the terms soft coral and gorgonian continue to be used to differentiate between morphological groups (and continues to be used in some classification schemata), continua of intermediate forms exist, and earlier taxonomic separations of the Alcyonacea into different groups have been abolished by most classifications (Bayer, 1981). Phylogenetic research suggests that further significant changes to the current classification may be warranted.

Most octocoral colonies are supported by sclerites embedded in the tissue, and a hydroskeleton or a proteinaceous and/or calcareous axis. Sclerites are minute calcareous structures typically less than 0.3 mm in length (range about 0.02 to >12 mm; Figure 3). Some species have neither sclerites nor other calcareous structures (e.g., some Xenidae). A few species (e.g., *H. coerulea*, *Tubipora musica*, and *Corallium*) have a solid skeleton. The rigid structure of these species contributes to habitat complexity on the reef during their life, and they may also contribute to reef framework and sedimentary deposits on their death. Some species of *Simularia* also contribute to reef structure and sediment stabilization by depositing massive trunks of consolidated sclerites that can reach decimeters across and meters in height.

Among the gorgonians, a wide variety of additional supporting structures are found. Their internal axes may consist of fused or unfused sclerites, sometimes bound by amorphous calcareous material, solid calcium carbonate, and/or a combination of collagen and gorgonin (a dark, hard proteinaceous material related to horn). For example, sections along the axis may alternate between horny and calcium carbonate materials (family Isididae), nodes and internodes (family Melithaeidae), or layers across the axes may consist of a gorgonin core surrounded by large amounts of calcareous material (family Ellisellidae). The shape and size of sclerites, the structure and material composition of the internal axes, and colony growth forms are the main features used for taxonomic analyses (Fabricius and Alderslade, 2001). Sclerites may be investigated by placing a small amount of tissue (1–3 mm<sup>3</sup>) onto a microscopic slide, and digesting the tissue with a few drops of concentrated bleach (sodium hypochlorite). Once the tissue is digested and bubble formation has ceased after a few minutes, a few drops of a glycerol and cover slip are applied for casual microscopic examination. To produce permanent slides, the sclerites are rinsed in freshwater and then in 95% ethanol. When all liquid is completely evaporated and the sclerites dry, an acid-free mounting medium and a cover slip are applied.

### Evolution and biogeography

Due to a lack of preservable features, very little is known about the evolution of octocorals. The Pennatulacea are an exception, with phylogenetic analyses presented by Williams (1993a, 1995). Williams postulates that the Pennatulacea as a group initially differentiated from shallow-water alcyoniid-like ancestors in the shallow waters of tropical oceans, and subsequently diversified and dispersed to all depths of the temperate and polar regions, as well as the tropics. The most primitive pennatulacean group Veretillidae show a range of similarities with some alcyonacean taxa, and like the alcyonaceans are most diverse in the Indo-Pacific at <100 m depth. Highly derived forms such as *Virgularia* and *Pteroeides* are sympatric with the more primitive taxa in the shallow-water tropics, while other highly derived forms such as *Chunella* and *Umbellula* are restricted to deep water. Some pennatulacean fossils date back to the Mesozoic.

There are still major gaps in the understanding of octocoral biogeography. In Indo-Pacific coral reefs, detailed octocoral studies include those from New Caledonia (Grasshoff, 1999), the Great Barrier Reef (Fabricius and De'ath, 2008), Japan (Benayahu, 1995), Palau, Micronesia (Fabricius et al., 2007), and South-Eastern Africa (Williams, 1993b; Benayahu et al., 2003). Despite the sparsity of available information, it appears likely the center of biodiversity for shallow-water reef-inhabiting octocorals coincides with that of other reef inhabiting organisms, namely the "Coral Triangle" that includes

Indonesia, Malaysia, and the Philippines. Very little taxonomic overlap exists between the Caribbean and the Indo-Pacific octocoral fauna.

### Biology and ecology

Octocorals include a moderately diverse range of species with widely contrasting biological properties. Life expectancy and growth rates of most soft corals and gorgonians are largely unknown. Being modular organisms, the relationship between colony size and age is weak, as colonies may show negative growth when torn by storm waves or damaged by moving rubble or predation.

After hard corals, octocorals are the second-most common group of macrobenthic animals on many Indo-Pacific and Caribbean coral reefs. On the Great Barrier Reef, octocoral cover averages 3–35% on outer reef slopes, but may be up to 70% in current-swept yet wave-protected environments such as channels between reefs or islands (Fabricius and De'ath, 2008).

Dispersal strategies vary greatly among species, and include asexual propagation and sexual reproduction. Asexual propagation may be based on the generation of daughter colonies at the terminal ends of stolons, or the budding of miniature colonies that fall of the mother colony and settle near-by. Fragmentation also occurs when a central section of a colony dies yet the edges survive and reorganize into complete colonies. Two modes of sexual reproduction exist: first, in "broadcasting" species the male and female gametes are released into the water column. After fertilization, the pelagic larvae are dispersed by currents until they settle some days to weeks later. Second, in "brooding" species the eggs are fertilized on or within the mother colony, and the resulting larvae develop on the colony surface until they detach and settle nearby some days later.

Despite being sessile and not having a protective skeleton, overall feeding pressure on octocorals appears remarkably low. The few known species to predate upon octocorals include some snails (e.g., the cowry shell *Ovula ovum*), nudibranchs, fish (e.g., the butterfly fish *Chaetodon melannotus*), and there is occasional grazing by young green sea turtles (*Chelonia mydas*) and echinoderms such the sea urchin *Diadema*. Many octocorals are effectively protected against predation, fouling by algae or overgrowth by neighboring organisms through feeding-deterrent, toxic, or allelopathic secondary metabolites. Some of these substances appear to be of pharmaceutical or bioactive value.

A range of epibenthic organisms are associated with octocorals. Amphipods are commonly found in large numbers on octocoral colonies, and some species of brittle star (Ophiuroidea), feather star (Crinoidea), shrimps, barnacles, ctenophores, and fish (gobies and pygmy sea horses) are exclusively found on the surface of some octocoral taxa. Most of these associates use the octocoral colony as a perch or for shelter; however, some of the epibenthos also appear to feed on octocoral mucus.

Octocorals are passive suspension feeders that filter particles from the water column, relying on currents to carry the food particles toward their polyps (Best, 1988; Fabricius et al., 1995; Ribes et al., 1998). Much of the food is therefore derived from phytoplankton, minute detrital particles, flagellates, and very small zooplankton: their simple stinging cells are unable to capture larger zooplankton. In addition, endosymbiotic algae (genus *Symbiodinium*, historically also called zooxanthellae) are found in about half of the Indo-Pacific reef-inhabiting octocoral taxa, and in most Caribbean octocorals. Zooxanthellae supply photosynthetically fixed carbon to the host, while the host in return provides nutrients and shelter to the algae. This finely tuned symbiosis between animal and alga depends on the availability of light for photosynthesis. Symbiotic (zooxanthellate or phototrophic) taxa include many representatives within the “true” soft corals (the Alcyoniina group), especially within the abundant families Nephtheidae, Alcyoniidae, and Xenidiidae, but also most Caribbean gorgonians (van Oppen et al., 2005). In contrast, most Indo-Pacific sea fans, and also several soft coral genera (e.g., *Dendronephthya*) do not contain zooxanthellae. These asymbiotic (azooxanthellate or heterotrophic) taxa are visually distinguished from their phototrophic relatives, which are typically brown, beige, or cream in color (Figure 1a, c), by their bright yellow, orange, red, pink, purple, or snow-white coloration (Figure 1b, d). Throughout their evolutionary history, groups of octocorals have repeatedly entered into and lost their association with endosymbionts (van Oppen et al., 2005).

The diversity of an octocoral community at a given site depends on three factors. First, the biogeographic location and colonization history of a region determines the regional species pool present. The diversity of octocorals in coral reefs strongly attenuates with latitude, and with distance away from the “coral triangle.” Second, environmental conditions determine what subset of the local species pool occurs at that locality. Abundances of particular taxa are strongly determined by the physical environment, especially light availability and water currents, which are both related to energy availability (Fabricius and De'ath, 2008). Azooxanthellate taxa are mostly found in low-light and high-flow environments, while zooxanthellate taxa require high light levels and relatively clear water. Azooxanthellate taxa tend to have lower abundances and more restricted geographic ranges than their zooxanthellate relatives, hence energy gains from symbiosis contribute to high local species richness in clear-water reef environments (Fabricius and De'ath, 2008). Third, at any point in time local and regional species richness also depend on disturbance history, specifically the nature and intensity of the disturbance, and the time since past disturbances have removed colonies. Major disturbances of octocoral communities are those from storms (with storm waves tearing off and damaging colonies), episodes of high water temperatures (leading to bleaching and mortality of zooxanthellate taxa), chronically reduced water clarity

(reducing photosynthesis), and high sedimentation events (smothering colonies or hampering larval settlement).

### Threats and conservation issues

Few octocorals are exploited for human use. Exceptions are *Tubipora* spp. (organ pipe coral) and *H. coerulea* (blue coral), the permanently brightly colored skeletons of which are used for ornaments and jewellery. They are also popular as aquarium species, and the trade of both species is regulated by the Convention on International Trade in Endangered Species (CITES). However, illegal collection of *Tubipora* spp. is wide-spread and in some regions this genus has become rare due to overharvesting.

Octocoral species are affected by the same threats that affect coral reefs globally, in particular climate change, poor land management, and destructive fishing methods. Like hard corals, most octocorals that contain zooxanthellae are highly susceptible to bleaching at high seawater temperatures, and many octocorals have been killed by previous mass bleaching events in many parts of the world. Some sea fans are also highly susceptible to diseases, especially when stressed from high temperatures and/or high nutrient exposure (Ward et al., 2007). Many taxa are also highly sensitive to exposure to increased turbidity, sedimentation, and eutrophication. High turbidity reduces the diversity of zooxanthellate taxa, but has little effect on the diversity of azooxanthellate octocorals (Fabricius and McCorry, 2006), suggesting that octocoral diversity is controlled by energy available for photosynthesis (Fabricius and De'ath, 2008). Macroalgal dominance from eutrophication and overfishing also negatively affect octocoral abundances and biodiversity.

### Summary/Outlook

With their bright colors and diverse sizes and shapes, octocorals greatly contribute to the stunning beauty of coral reefs. Despite their abundance and visual appeal, the taxonomy, phylogeny, biology, and ecological roles of octocorals remain insufficiently understood. Despite these large knowledge gaps, it is undisputed that any measure taken to safeguard the reefs' hard corals will also be effective to protect octocorals as well as the numerous other invertebrate and vertebrate species that inhabit the World's coral reefs.

### Acknowledgments

Many thanks to Phil Alderslade for improving the manuscript.

## OIL AND GAS RESERVOIRS AND CORAL REEFS

J. Frederick Sarg

## Synonyms

Carbonate buildup reservoir; Coral reef reservoir; Reef buildup reservoir

## Definition

Coral reef reservoir: A subsurface volume of coral reef boundstone and associated skeletal grainsupportstone (i.e., packstone–grainstone) that has sufficient porosity and permeability to permit the accumulation of crude oil or natural gas under adequate trap conditions.

## Reservoir characteristics of coral reef systems

Carbonate reservoirs are important contributors to world oil and gas production and contain more than one-half of global discovered, recoverable hydrocarbons (Roehl and Choquette, 1985). Reef and reef-related deposits comprise a significant proportion of these reservoirs, most prominently in carbonate systems of Siluro-Devonian, Cretaceous, and Neogene age. The Neogene-aged reservoirs are commonly composed of coral reef and their associated deposits. In general, the original textures of the carbonate sediments and their early diagenetic pathways are determinants of the likelihood and extent of carbonate reservoir rocks. Primary sedimentary textures related to depositional environment, provide the initial matrix pore system and generally determine the extent of the prospective reservoir. The vast majority of the carbonate reservoirs have undergone modification of primary pore space because of syn- to post depositional diagenesis. Both occlusion and enhancement may occur. Preservation of reservoir-quality pore systems is most commonly the result of cessation of occluding processes such as cementation (i.e., early marine, meteoric phreatic, and/or burial), and compaction, rather than the result of pore enhancement from processes like karst solution or dolomitization, although these can be important processes locally and during certain time periods (e.g., icehouse times).

Coral reef and related reservoir-prone deposits are most commonly comprised of thick to massive bedded, reef boundstones in platform margin and platform interior patch reef settings and skeletal rudstones, floatstones, grainstones, and packstones interbedded with the boundstones and in fore-slope debris. Reef deposits occur over relatively small areas (square kilometers to 10s of square kilometers), and range in thickness from meters to

Molds after gastropods and bivalves, Vugs solution enlarged, irregular holes.

100s of meters (up to a 1,000 m or more), and can have very thick oil columns. The most common depositional pore types in reefs and reef associated beds include interparticle, intraparticle, and growth-framework shelter porosity (see Choquette and Pray, 1970; Lucia, 1999; Lónóy, 2006 for pore classifications) (Figures 1 and 2). These pores generally range in size from mesopores (50–100  $\mu\text{m}$ ) to macropores (>100  $\mu\text{m}$ ), and can have a patchy (e.g., shelter and intraparticle) to uniform (e.g., interparticle) distribution (Lónóy, 2006). Where affected by karst dissolution, pore types include moldic macropores (>30–30  $\mu\text{m}$ ), vugs, and solution-enlarged fractures. Porosity values range from low (<5%) to high (>30%), as does permeability (<100 md to Darcy's). Reef reservoirs are generally very heterogeneous. Porosity ranges from patchy to uniform distribution over moderately large areas, resulting in variable interconnectivity and in many fields, tortuous fluid pathways. Nevertheless, these reservoirs are some of the most prolific in the world (Trice, 2005).

### Reef reservoirs and climate

Climate is a major controlling factor on early diagenesis and pore system history. Greenhouse and icehouse climatic conditions effect carbonates differently (Read, 1995; Trice, 2005). Greenhouse times are characterized by widespread flooding of continental shelves, and by low amplitude sea level changes, typically from 10 to 50 m (Goldhammer et al., 1990; Koerschner and Read, 1989; Wright, 1992; Read, 1995). Greenhouse reservoirs develop in reef and carbonate sand shoal lithofacies that stack in aggradational or gently prograding ramp geometries. Reservoirs are relatively homogeneous, and form extensive sheets. Vertical communication through pore systems is dominated by primary porosity. Small sea level

falls prevent significant drops in water tables, and reduce meteoric diagenetic effects. Long-term exposure (100s kyr) at sequence boundaries can be more significant, and can lead to enhanced meteoric diagenesis, soil formation, and/or silcrete/caliche caps that provide reservoir baffles and barriers. Reef reservoirs of Devonian and Cretaceous age exhibit many of these characteristics.

Ice-house times are characterized by high amplitude (60–100+ m), high frequency sea level fluctuations. Carbonate productivity can vary over short distances, resulting in considerable lateral variability in thickness and internal facies distribution. Deeper muddy subtidal facies, shallow shoal water grainy facies, and facies exhibiting subaerial exposure may be juxtaposed over short lateral distances. High-frequency cycles show juxtaposition of deep water muds, shallow water facies, and subaerial emergence features (Read, 1995), resulting in vertical baffles and barriers to flow. In arid settings, caliche or silcrete will form extensive nonporous caps to depositional cycles. Ice-house reservoirs thus can be more compartmentalized than greenhouse reservoirs.

Icehouse conditions will produce disconformity bounded sequences, 10–100s m thick. High amplitude, sea level fluctuations are significant and cause large-scale lateral and vertical migration of diagenetic zones. Facies deep within platforms are subjected to repeated interaction with marine and meteoric fluids in vadose and phreatic environments. The extent of karst formation is dependent on the climatic conditions at the time of exposure (Perkins, 1977; Beach, 1982). Humid conditions lead to considerable leaching of less stable carbonate minerals (i.e., aragonite and hi-Mg calcite) forming significant secondary porosity (i.e., molds, vugs, caves, caverns, etc.) (Loucks, 1999). Arid settings tend to allow preservation of original primary porosity.

**Oil and Gas Reservoirs and Coral Reefs, Figure 3** (a) Natuna L subsea depth structure in feet (from Eyles and May, 1982). (b) Natuna sequence stratigraphy showing well correlations. Platform consists of alternating thick shallowing upward highstands (increasing porosity) (i.e., highstand systems tracts) and thin deepening upward transgressive (decreasing porosity) deposits (i.e., transgressive system tracts). Highstand deposits show porosity enhancement beneath subaerially exposed sequence boundaries (i.e., age date surfaces) (modified after Rudolph and Lehmann, 1989).

**Oil and Gas Reservoirs and Coral Reefs, Figure 4** Thin section photomicrographs of Natuna reservoir lithofacies, plane-polarized light. (a) Coral-red algae boundstone in a grainstone matrix. A moldic, mud-filled coral encrusted by red algae to left. Light gray areas are moldic and vuggy porosity. (b) Coral-red algae-echinoderm packstone/grainstone. (c) Coral-red algae-echinoderm grainstone. Moldic porosity shown in light gray areas (modified after Rudolph and Lehmann, 1989).

The lack of meteoric water allows primary pores to remain open and allows preservation of permeable networks. The Neogene reef reservoirs of the Australasian region are characterized by humid karst-modified primary pore systems. Because of their similarities to Pleistocene and Modern reef systems (Melim et al., 2001) and their significance as oil and gas reservoirs, they are summarized below.

### Neogene reef platform oil and gas reservoirs

The late Oligocene through Miocene was a period of widespread coral/algal carbonate platform development in the Australasian region (Epting, 1980; Fulthorpe and Schlanger, 1989; Ehrlich et al., 1993; Saller et al., 1993; Gucci and Clark, 1993; Sun and Esteban, 1994). These Neogene reef platforms have been the targets of hydrocarbon exploration and there have been numerous discoveries (Table 1) [i.e., Malaysia: central Luconia (Ho, 1978; Epting, 1980, 1989; Sulaiman, 1995); Philippines: Nido (Withjack, 1985) and Malampaya (Grötsch and Mercadier, 1999); Indonesia: Arun (Abdullah and Jordan, 1987; Jordan and Abdullah, 1992), northwest Java Sea (Yaman et al., 1991); Ramba (Longman et al., 1987); South Lho Sukon (Maliki and Soenarawi, 1991), Natuna (May and Eyles, 1985; Rudolph and Lehmann, 1989); China: Liuhua, Pearl River (Moldovanje et al., 1995)].

Two of these fields, Natuna L (Rudolph and Lehmann, 1989) (Figures 3 and 4), and Jintan, Luconia Province (Vahrenkamp et al., 2004) (Figure 5) illustrate aspects coral reef reservoir architecture and lithofacies. Both of these field examples are isolated reef platforms of middle to late and middle Miocene age, respectively. Reservoir columns are approximately 300 (Jintan) to 1,000 (Natuna) meters in thickness. Reservoir lithofacies range from coral-algal boundstones, rudstones, floatstones, grainstones, and packstones (Figures 1 and 3). Bioclasts also include abundant foraminifera, mollusks, and echinoderms. Porosity ranges from 5 to 40%, and pore types are dominantly Vug, Moldic (Mo), and Interparticle (BP). Each platform has undergone periodic and significant sub-aerial exposure leading to secondary porosity enhancement (Figures 3 and 4). The best reservoir quality occurs in highstand systems tract deposits that have been subjected to subaerial exposure. These reservoirs tend to stack vertically and extend across each platform (Figures 3 and 5).

### Summary

Carbonate reservoirs are important contributors to world oil and gas production (>50% of global reserves), and reef reservoirs are a significant proportion of these reservoirs. They are particularly abundant in the Siluro-Devonian, Cretaceous, and Neogene time periods. The Neogene-aged reservoirs are commonly coral reef and associated

**Oil and Gas Reservoirs and Coral Reefs, Figure 5** (a) Reflection and (b) acoustic impedance section through Jintan field. Synthetic seismic logs show good match with seismic. Horizons (H1B, H2A, etc.) define reservoir zones shown on acoustic impedance (Z1a, Z2a, etc.). Low impedance areas (blue/green) (i.e., higher porosity) show both vertical and lateral connectivity (from Vahrenkamp et al., 2004).

grainsupportstone deposits. Reef reservoir pore systems are generally characterized by some combination of primary depositional, and diagenetic pore types. Porosity ranges from patchy to uniform, resulting in vertical and horizontal heterogeneity. Climate controls the effects of early diagenesis. Greenhouse reservoirs show less effect of subaerial dissolution and greater internal continuity. Icehouse reservoirs that have been affected by humid karst conditions show significant pore system modification. The Neogene coral/algal

reservoirs are most similar to modern reef systems and exhibit dissolution modification of their pore systems.

### Definition

Ooids are spherical-sub spherical grains, consisting of one or more regular concentric lamellae around a nucleus, usually a carbonate particle or quartz grain.

Sediment composed of ooids is referred to as an *oolite*. The term ooid has been restricted to grains less than 2 mm in diameter and the term pisoid (formerly pisolith) is used for similar grains of a larger diameter. *Coated grain* is a general term frequently used for ooids and pisoids, and includes *oncoids*, grains with a microbial coating.

Ooids typically form in agitated shallow waters of sub-tropical seas where they are frequently moved as sand-waves, dunes and ripples by tidal and storm currents, and wave action. They are commonly found in association with reefs and reefal limestones; thus they often form along shelf-margins (e.g., the Bahamas), but they also occur in tidal-deltas and beach-barriers of shallow ramps (e.g., Trucial Coast, Arabian Gulf).

The majority of modern ooids range from 0.2 to 0.5 mm in diameter, are composed of aragonite and have a high surface polish. The characteristic microstructure is a tangential arrangement of acicular crystals, 2  $\mu\text{m}$  in length. Rarely ooids (and pisoids) form in quieter-water marine locations, such as lagoons and tidal flats, where a radial fabric is more common. Ooids can form in areas of strong wave action in lakes, where they usually have a dull, commonly, cerebroid (bumpy) surface. They may be composed of aragonite or calcite, or be bi-mineralic (low-Mg calcite–aragonite). These may be associated with stromatolite bioherms.

### Ancient marine ooids

Ooids in the rock record are generally composed of calcite (low Mg), but of these some were originally calcite (possibly high Mg), whereas others were originally aragonite. Primary calcite ooids, whether in high-energy or low-energy facies, typically have a radial texture of wedge-shaped, fibrous crystals, with an extinction cross under

crossed polars. Ancient ooids originally of aragonite will have been altered during diagenesis to a greater or lesser extent. Commonly, the aragonite has been dissolved out completely, to leave oomoulds, or these holes may be filled with calcite cement. Some ooids have a fine-grained micritic texture, mostly the result of micritisation by endolithic microbial organisms.

### Origin of ooids

Current ideas for the origin of ooids invoke inorganic or biochemical processes. For the former, the sea water in shallow tropical areas is supersaturated with respect to  $\text{CaCO}_3$ , so that this, together with water agitation,  $\text{CO}_2$  degassing and elevated temperature, is considered sufficient to bring about carbonate precipitation on nuclei. In a biochemical origin, the microbial processes in the organic mucilage (EPS) that coats and permeates the ooids create a microenvironment conducive to carbonate precipitation. The factors determining the primary mineralogy of ooids are water chemistry, especially  $P_{\text{CO}_2}$ , Mg/Ca ratio, carbonate saturation, and possibly the degree of water agitation. It is believed that aragonite and high-Mg calcite ooids are precipitated when  $P_{\text{CO}_2}$  is low and Mg/Ca ratio high, with opposite conditions for low-Mg calcite ooids. High carbonate supply, as would occur in high-energy locations, is thought to favour aragonite precipitation over high-Mg calcite.

There is a secular variation in the original mineralogy of ooids through the Phanerozoic, with aragonitic ooids, which may be associated with calcitic ooids (likely high-Mg calcite originally) in the late Precambrian/early Cambrian, mid-Carboniferous through Triassic and Tertiary to the Recent, and calcitic ooids (presumed to have low-to-moderate Mg content) dominant in the mid-Palaeozoic and the Jurassic–Cretaceous. This pattern, which correlates with the first-order, global sea-level curve, suggests a geotectonic mechanism(s) causing subtle variations in  $P_{\text{CO}_2}$  and/or Mg/Ca ratio in seawater. High sea-level stands, correlating with calcite seas, are times of high rates of sea-floor spreading, and high  $P_{\text{CO}_2}$  from increased metamorphism at subduction zones, and low Mg/Ca ratio from increased extraction of  $\text{Mg}^{2+}$  at mid-ocean ridges through seawater pumping.

## PACIFIC CORAL REEFS: AN INTRODUCTION

James E. Maragos<sup>1</sup>, Gareth J. Williams<sup>2</sup>

<sup>1</sup>U.S. Fish and Wildlife Service, Honolulu, HI, USA

<sup>2</sup>Victoria University of Wellington, Wellington, New Zealand

### Introduction

This entry introduces coral reefs and associated archipelagos within or facing the Pacific Ocean, including those not sheltered behind adjacent western seas (Japan, Yellow, South China, Sulu, Celebes, Banda, Arafura); continents (Australia, Asia), and sub-continents (SE Asia, New Guinea). The Great Barrier Reef of Eastern Australia is within the Pacific Ocean but, like other regions, is covered in more detail in separate entries. A total of 47 archipelagos and isolated reefs and islands under the jurisdiction of 31 nations and territories in the Pacific are covered here and listed in [Table 1](#). The location and current names of most of the archipelagos and some of the nations are shown in [Figure 1](#). It is impossible to list and show all the governments and archipelagoes on one map or accurately estimate the number of tropical islands and reefs in the Pacific. However, there are likely more than 10,000 islands and associated reefs, far more than reported in [Table 1](#), which focuses mostly on the larger inhabited Pacific islands.

The Pacific supports the largest tropical and subtropical habitat for coral reefs in the world at about 58% of the global total, amounting to approximately 88 million km<sup>2</sup> between latitudes of 30° N to 30° S, based upon distance and area calculations of Google Earth imagery. This compares to about 35 million km<sup>2</sup> of habitat for the Indian Ocean, about 17 million km<sup>2</sup> of habitat for the Gulf of Mexico-Caribbean Sea, and 13 million km<sup>2</sup> of habitat for SE Asia. Along the Equator, the Pacific stretches from

127° E (off the eastern coast of Haimahera Island, north of New Guinea Island) to 80° W (off the western coast of Ecuador near Quito), a distance of 16,900 km and accounting for 42% of the circumference of the earth. Although the Pacific's huge size supports much larger numbers of coral reefs, tropical islands, large reefs, and habitat compared to those in the Indian Ocean and Gulf of Mexico-Caribbean Sea, the Pacific island number and size totals are less than those within SE Asia; much of the tropical and subtropical habitat in the Pacific is devoid of islands and reefs.

### Categories of reefs in the Pacific Ocean

All coral reefs begin as coral and/or coralline algal communities either along the sides and tops of emergent volcanoes near or above the sea surface within the Pacific Ocean basin or on preexisting substrates of the continents or continental islands bordering the Pacific. Periods of subsequent subsidence or uplift, tectonic plate movements, sea-level rises and falls, and other epochs of unfavorable ocean temperatures and chemistry during the Mesozoic and Cenozoic likely led to massive drowning, dissolution, and subduction of many ancient reefs. Not all of these were restored following the return of favorable conditions for their growth and survival. This chapter covers only living Pacific reefs comprising:

1. *Fringing reefs* – coral reefs that grow out and upwards to the sea surface directly from the shoreline of mostly volcanic or continental islands ([Figure 2](#)), starting out as aprons that may eventually encircle the fringes of islands and form shallow reef crests or flats.
2. *Barrier reefs* – linear offshore reefs that encircle subsiding or emerging volcanic islands offshore or on continental shelves beyond shallow lagoons that separate the barrier reefs from the island or continent ([Figure 3](#)).

**Pacific Coral Reefs: An Introduction, Table 1** Comparing 47 coral reef archipelagos and single islands in the Pacific Ocean. Explanations: **bank** = submerged reef, **lag** = lagoon or marine lake, **areef** = atoll reef, **barr** = barrier reef, **low** = low reef island, **atol** = atoll, **lime** = raised limestone island or atoll, and closed atolls, **volc** = volcanic island with fringing reef, **all is** = total of all main islands, **tren** = tectonic trench nearby and likely contributing to island's formation, **cont** = continent or continental island, **bas** = basalt or oceanic island, **hot** = island or reef near to and likely formed over an oceanic hotspot, **1** (or more) = present, **0** = absent, and **nd** = no data. Area units = km<sup>2</sup>. Jurisdictions listed are at the highest independent national levels. Jurisdiction and archipelago names often differ, and archipelago names in brackets are those used during the twentieth century before political independence. Total number of islands and reefs are underestimated and focus on main inhabited islands, especially in the Solomon, Papua New Guinea, New Hebrides, Vanuatu, and Fiji Islands. **Pacific Coral Reefs: An Introduction, Figure 1** Mercator projection map of the marine geology and named archipelagos, trenches, and fracture zones in the Pacific Ocean Basin between Latitudes 30° N and 30° S (Source of map: National Geographic Society).

**Pacific Coral Reefs: An Introduction, Figure 2** Fringing reefs encircling the Whitsunday Islands (20° 19'S, Latitude and 145° 56'E, Longitude) inside the Central Great Barrier Reef off north east Australia (Source Map Data Sciences Pty. Ltd. PSMA Image (2009) : Digital Globe (2009), Europa Technologies (2009) and Google Earth (2009).

3. *Submerged reefs* – living reefs on the tops of subsided volcanoes that are within water depths of 0–30 m, that may cause waves to break upon them, but that do not support emergent reefs or islands (Figure 4).
4. *Atoll reefs* – similar to the above except the reefs reach near the sea surface and encircle a protected lagoon without supporting emergent vegetated islands (Figure 5).
5. *Atolls* – similar to the above except that the atoll supports one or more vegetated islets and its reefs partially or wholly encircle a lagoon and allow regular surface interchange of waters between the ocean and lagoon (Figure 6).
6. *Low reef islands* – Similar to atolls in that they grow upwards off the crests of subsiding volcanoes, reach the sea surface, and support one or more emergent vegetated reef islets, but lack the size or shape to support a perimeter reef encircling a lagoon (Figure 7).
7. *Raised limestone islands and atolls* – similar to atolls and reef islets except that living reefs are limited to the submerged perimeter fringes facing the ocean. The interior parts are raised above sea level to elevations where reef builders (such as corals, coralline algae) cannot survive due to constant aerial exposure, causing the emergent part of the reef to weather and erode, often to limestone, and often creating inland marine lakes that lack regular surface water exchange with the ocean (Figure 8).
8. *Closed atolls* – similar to raised atolls except that they are near sea level but with interior marine lakes completely land-locked by the islands and blocking all surface seawater exchange with the ocean (Figure 9).
5. *Southern subtropical Pacific* – consisting of small volcanic and reef islands north of New Zealand and east of Australia, including the Kermadec, Elizabeth, Middleton, Norfolk, and Lord Howe islands and reefs.
6. *Southwestern continental border* – consisting of the continental shelf islands and reefs from the southern end of the Great Barrier Reef to the Torres Strait.
7. *Southwestern tropical Pacific* – dominated by many large and small volcanic continental islands, numerous raised reef islands, and approximately 100 atolls and reef islets in Papua New Guinea, Solomon Islands, Vanuatu, Fiji, Tonga, Samoa, and New Caledonia.
8. *Northwestern tropical Pacific* – consisting of two dozen volcanic islands, several hundred raised reef islands, and about 100 atolls and reef islets including the Marshall Islands, Mariana Islands, Gilbert [Tungaru] Islands of Kiribati including Nauru and Banaba, Caroline Islands (Palau and Federated States of Micronesia), and a few offshore reefs and atolls east of the southern Philippines and Indonesia.
9. *Northwestern subtropical continental border* – including the Ogasawara [Bonin], Ryukyu, and Minami Torishima [Marcus] islands of Japan; Taiwan; and other small islands and reefs in open South China Sea north of the Philippines.

The archipelagos and isolated islands in the Pacific can be grouped into about nine clusters based upon biogeography, geology, and cultural history (Figure 10). Beginning at due north and moving clockwise, these consist of:

1. *Subtropical Hawaiian Islands* – consisting of Hawaii and Johnston Atoll, including two dozen small to large volcanic basalt islands, several atolls, and two low reef islands.
2. *Eastern tropical continental border* – consisting of one closed atoll (Clipperton) and several volcanic island clusters off the continental shelves and slopes of the Americas from Mexico through Costa Rica and Panama to Ecuador and including the Galapagos.
3. *Southeast tropical insular Pacific* – consisting of scattered basalt volcanic islands, a hundred atolls and reef islets, and one raised limestone island (Makatea), and one raised atoll (Henderson) collectively within French Polynesia, Pitcairn, Rapa Nui, and Sala y Gomez.
4. *Central tropical Pacific* – consisting of about 50 atolls and reef islets and a few raised limestone and small basalt volcanic islands south of Hawaii and north of Samoa, and including the Phoenix, Line, Cook, Tokelau, Ellice [Tuvalu] archipelagos, Niue Island, and Rose Atoll.

## Geology

Most of the contemporary Pacific Ocean is bounded by a “Ring of Fire” (Figure 11a), with dozens of volcanoes, deep ocean trenches, and mountain ranges lining the border that separates the oceanic (basalt) crust of the central Pacific Ocean basin from adjacent continental crust of islands and continents. About 200 million years ago, the Pacific Ocean was part of a single ancient global ocean before tectonic activity during the Permian began to fragment it along with the single continent (Pangaea) into smaller continental and ocean plates that have continued to collide and/or drift apart to this time. Eventually this led to segregation of the Pacific from the Indian Ocean and dissecting and fragmenting continental and oceanic crusts between the two emerging oceans to create what is now SE Asia.

Over the past 100 million years, the massive Pacific Ocean plate has continued to produce and move new crust in a northwestern direction via convection flow beneath the East Pacific Rise and collisions with the adjoining Nazca Plate off the west coast of South America. The Pacific plate is continuing to move slowly towards the trenches of NE Asia, Siberia, and the Aleutians where eventually it is subducted under them. Additionally, the Asian continental plate is encroaching on the Pacific Ocean Plate from the NW, the Australian continental plate is encroaching from the west, and the two American continental and Nazca plates from the east, creating massive continental mountain ranges and trenches bordering the Pacific plate. These movements and collisions generate earthquakes, landslides, volcanism, tsunamis, uplift, and

**Pacific Coral Reefs: An Introduction, Figure 3** Taha'a Island and surrounding barrier reef (June 2000 image; 16° 38' S Latitude and 151° 30' W Longitude) and 10 km scale bar, Society Islands, French Polynesia (Source: Europe Technologies Image (2009), DigitalGlobe (2009), and Google Earth (2009)).

other seismic events. As the broad Pacific plate creeps towards the NW, parts of it move at different rates and directions, creating fracture zones, volcanic hotspots, earthquakes, subsidence, emergence, and flexures that have further contributed to the rise and fall of dozens of volcanic archipelagos at hotspots on the plate over the past 80–100 million years (Figures 11a and b). Overall, central Pacific archipelagos are now generally older towards the NW and younger towards the SE margins of the plate. Conversely, larger and more numerous islands are concentrated in the SW tropical Pacific but are virtually absent in the tropical and subtropical East Pacific. Deep ocean trenches separate the continents from the Pacific Ocean around most of the latter's perimeter. Moreover, much of the southwestern Pacific region is bisected by several trenches stretching from the western end Samoa through Tonga, Vanuatu, Solomons, etc. (see Schellart et al., 2006).

#### **Oceanographic and climatic processes affecting Pacific coral reefs**

A system of circular surface ocean currents, called gyres, dominates circulation in the Pacific and other large oceans

(Figure 12). The gyres move clockwise in the northern hemisphere and counterclockwise in the southern hemisphere, and greatly influence the diversity of reef life and distribution of Pacific reefs. In the northern hemisphere, the cold California Current runs south along the west coast of North America from Alaska to southern Mexico and then turns west where it is named the North Equatorial Current. As this current runs west along the broader Pacific in low latitudes, it heats up before turning north, named the Kuroshio Current that runs along the east coast of Japan and Siberia, bathing the reefs at higher latitudes with warmer waters. Then the current turns east off Siberia where it is named the Subarctic Current that cools off as it travels east at high latitudes towards Alaska before it turns south as the California Current again, continuing its circular clockwise movement in the northern Pacific.

The gyre in the southern hemisphere is a mirror image of the northern gyre. The cold Peru Current runs north along the west coast of South America, and turns west off Ecuador where it is named the South Equatorial Current that heats up along its long journey across the South Pacific at low latitudes. Some of this current moves west through the Torres Strait, but most runs through

**Pacific Coral Reefs: An Introduction, Figure 4** Large complex of submerged reefs with 50 km scale bar ( $8^{\circ} 46' S$  Latitude and  $149^{\circ} 59' E$  Longitude), off the Western D'Entrecasteaux Islands, Papua New Guinea (Source: U.S. Geological Survey (2009), Europa Technologies (2009), and Google Earth (2009)).

**Pacific Coral Reefs: An Introduction, Figure 5** Example of atoll reef at Kingman Reef National Wildlife Refuge, Line Islands ( $6^{\circ} 24' N$  Latitude and  $162^{\circ} 24' W$  Longitude). Length of reef is 15 km (Source of image: NASA and Lead Dog Consulting).

**Pacific Coral Reefs: An Introduction, Figure 6** Example of an atoll at Hereheretue Atoll, October 2006 ( $20^{\circ} 53' S$  Latitude and  $144^{\circ} 58' W$  Longitude) with a 3 km scale bar, Tuamotu Islands, French Polynesia (Source of image: Europa Technologies (2009), DigitalGlobe (2009), and Google Earth (2009)).

**Pacific Coral Reefs: An Introduction, Figure 7** Example of a low reef islet at Flint Island, March 2009 ( $11^{\circ} 26' S$  Latitude and  $151^{\circ} 49' W$  Longitude), with a 5 km scale bar at the southern end of the Line Islands (Source of image: DigitalGlobe (2009), Lead Dog Consulting (2009), Geoeye (2009), and Google Earth (2009)).

**Pacific Coral Reefs: An Introduction, Figure 8** Example of a raised limestone island at Banaba [Ocean] Island, April 2005 (00° 52' S Latitude and 169° 32' E Longitude), west of the Gilbert Islands and with a 3 km scale bar (Source: DigitalGlobe (2009) and Google Earth (2009)).

the large islands of the SW Pacific before turning south off NE Australia and is known as the East Australia current that helps to extend corals and reefs as far south as Brisbane. Then at high latitudes, the current turns east to join the broad, cold West Wind Drift that encircles the globe north of Antarctica. A branch of the West Wind Drift moves towards South America and turns north off Chile and is known as the Peru Current again, continuing the gyre's circular counterclockwise cycle.

The forces that drive these currents are heat exchange between low and high latitudes, the NE trade-winds in the northern tropics, the SE trade-winds in the southern tropics, and the rotating Earth's Coriolis Effect (describing mathematically the deflection of moving formations and masses, i.e., winds, ocean currents, clouds, aircraft, etc., caused by their inertia relative to the earth, a non-inertial uniformly rotating frame of reference). Trade-winds at the sea surface act to drag and mix the surface waters, pushing up sea level on the western ocean boundary to a slightly higher elevation vis-à-vis the eastern ocean boundary of the Pacific. The movement of both the NE and SE trade-wind systems towards low latitudes eventually causes them to collide and then rise skyward along an atmospheric band at about 5° N Latitude. These air masses then cool off and drop large amounts of rain in

a zone where surface winds are weak. This band of wet calm surface waters is the Inter-tropical Convergence Zone (ITCZ). The ITCZ weakens, strengthens, and shifts north and south depending on the strength of the trade-winds and the seasons.

Because the surface trade-wind drag is weak or absent beneath the ITCZ, a return flow of ocean water moving "down-slope" from the elevated western Pacific to the lower eastern Pacific is maintained as the North Equatorial Countercurrent. There is also a smaller South Equatorial Countercurrent at approximately 8° S Latitude and a sub-surface Equatorial Undercurrent that also runs west to east at the Equator. The eastward flow of water in these currents transports the larvae of many reef species from the biodiversity-rich western Pacific to the central and eastern Pacific. The warm water currents along the western boundary of the Pacific help to extend the range of many reef species to higher latitudes. Conversely, the cooler waters off the eastern boundary of the Pacific off the Americas may be another reason why reef development is generally poor in the East Pacific. All of the above current and wind systems are essential for exchanging heat between cooler polar areas and warmer tropical areas of the ocean and maintaining steady and predictable temperature regimes for corals and other reef life. Conversely,

**Pacific Coral Reefs: An Introduction, Figure 9** Example of a closed atoll, Clipperton Island ( $10^{\circ} 18' \text{ N}$  Latitude and  $109^{\circ} 13' \text{ W}$  Longitude) and its marine lake SW of Mexico. Clipperton is one of the most northeastern reefs in the Pacific Ocean (Source: Europa Technologies (2009), DigitalGlobe (2009), NASA (2009), and Google Earth (2009)).

when the wind systems break down during El Nino Southern Oscillations (ENSO) at low latitudes, water temperatures rise, causing corals to bleach and/or die, and slowing down the flow of currents vital for survival of many migratory marine organisms including fish and sea-birds (see entry “*Climate Change and Coral Reefs*”).

Tropical cyclones are also concentrated along specific “alleys” in the western and eastern central Pacific, and their effects are sufficient to limit the three-dimensionality, growth, and biodiversity of many reefs, especially in the Philippine, Taiwan, Mariana, Caroline, Papua New Guinea, Solomon, Samoa, and Cook archipelagos, and lesser so in most other Pacific archipelagos.

### Geography and biogeography of the tropical Pacific Ocean

The oceanic, climatic, and geological history of the Pacific Ocean has led to the contemporary distributional patterns of its islands, reefs, and dominant reef life as showed by Figures 11a and b:

1. Mostly, atolls and reef islands dominate the central Pacific along an axis from the Pitcairn and Tuamotu Islands at the SE and Marshall Islands and Marcus Island at the NW end of the axis (Figure 13). This region of the ocean is geologically stable, allowing

ancient volcanic islands to subside and allow formation of atolls, a dozen barrier reefs, and reef islands in accordance with Darwin’s theory.

2. Numerous volcanic islands of continental origin are to the west and south of oceanic basalt islands to the north and east. Many of the SW Pacific islands are large, representing the consequence of considerable tectonic activity over long time periods (Figure 1).
3. Numerous raised limestone islands along the west Pacific boundary and isolated volcanic islands with limestone caps in the central Pacific populate the Pacific Ocean. This is likely the result of collisions between the Pacific, Asian, and SE Asian plates, causing the Pacific crust to buckle and push coral reefs above sea level, creating volcanic island arcs above the subduction zones (Figure 14).
4. Smaller high-volcanic island chains and seamounts are scattered haphazardly over the tropical Pacific crust near a combination of hotspots, fracture zones, and flexures that allow volcanism to penetrate upwards through to Pacific crust to form islands that may later subside and serve as the substrates for a variety of coral reefs (Figures 11a and b).

At a Pacific-wide scale are vast expanses of the tropical Pacific that lack islands and coral reefs, particularly the eastern Pacific (Figures 11a and b), while the SW Pacific

**Pacific Coral Reefs: An Introduction, Figure 10** The location of the Eastern Pacific Barrier and the nine clusters of island archipelagos and coral reefs in the Pacific Ocean as explained in the text. (1) Subtropical Hawaiian Islands, (2) Eastern Continental Tropical Border, (3) Southeast Tropical Insular Pacific, (4) Central Tropical Pacific, (5) Southern Subtropical Pacific, (6) Southwest Tropical Continental Border, (7) Southwest Tropical Pacific, (8) Northwest Tropical Pacific, and (9) Northwest Subtropical Continental Border.

archipelagos have exceptionally high densities and larger coral reef habitats. The large timeframe and spatial distance of separation of East Pacific reefs from the rest of the reefs in the Central and Western Pacific has led to differentiation in evolution of species of corals and perhaps other reef-dwelling organisms. The broad zone between the two subregions lacking islands and reefs is referred to as the East Pacific Barrier. Additionally, there are still substantial distances between many of the archipelagos in the central and western Pacific, and their separate histories have also led to lesser levels of differentiation of their biological and geological characteristics and biodiversity. Most conspicuous is that the richness of coral reef and related marine species increases when moving from east to west across the Pacific. This increasing trend towards the western Pacific applies to all coral reef and related shallow-water tropical biota for which sufficient data are available, including: reef building corals, reef fishes (Figure 15), other reef invertebrates, algae, sea grasses, and mangroves.

Ongoing research, including that of Coral Geographic scientists are now compiling patterns for coral species richness at the archipelagic scale and have further proposed a “coral triangle” area where coral diversity reaches its highest global levels, including SE Asia and the SW Pacific areas of the Solomons and Papua New Guinea. The pattern of increasing species that totals towards the west is generally maintained at the archipelagic level throughout the Pacific (Figures 16). However, recent

research and analyses by the present authors covering more than 2,200 site surveys at 70 reefs of various types in the Central Pacific reveal that there is significant small-scale heterogeneity between reefs based upon the coral species richness and the complement of coral species reported at each (Figures 17 and 18). Among these reefs were found 25 significantly different clusters, including substantial differences in species compositions and richness between adjacent reefs. Although data analyses had not been completed, the principal factors explaining these clusters appear to be:

- Latitudinal proximity to the North Equatorial Countercurrent
- Longitude (distance from the “coral triangle”)
- Size of each reef or island
- Proximity to the nearest reef
- Size of the nearest reef, and
- Type of reef

These factors may help explain how especially geographic isolation, reef size, proximity to other reefs, and boundary currents can contribute substantially to our understanding of the biogeography of corals and their patterns of biodiversity, dispersal, and endemism throughout the tropical Pacific. However, these same factors may have different effects or be less influential for other reef biota, especially fishes that have greater mobility during both their adult and larval stages, and to algae that produce spores that remain viable over long time periods and distances. In

the past, theories of radiation and accumulation have been put forth to explain the broader scale biodiversity levels in the western Pacific, but these are insufficient for explaining patterns at smaller spatial scales (Maragos and Williams, in preparation). Certainly there is mounting evidence that the “coral triangle” region has contributed many of the species in the Pacific, but it is also clear that localized endemism and speciation at isolated reefs have also contributed additional species within the distant and isolated corners of the Pacific Ocean.

### Early cultural settlement of the central Pacific Ocean

Linguistics, oral history, legends, field archaeology, radio-carbon dating, artifacts (fish hooks, pottery, etc.), pollen

analyses, and molecular analyses suggest that there are three broad cultural groups that settled within the insular tropical Pacific, also known as Oceania, after the last glacial recession about 10,000 year ago. These are still the principal cultures resident in most of the islands of Oceania today (Figure 19):

- *Melanesia*. Settlers first reached the SW Pacific Islands of Fiji, New Caledonia, Papua New Guinea, Solomon Islands, Vanuatu more than 10,000 years ago from Southeast Asia and the Indian Ocean regions (Bellwood 1978; Rainbird 1994).
- *Micronesia*. Settlers from the Philippines first reached the NW Pacific islands about 5,000 years ago beginning with the Mariana Islands and then to the Caroline,

**Pacific Coral Reefs: An Introduction, Figure 11** (a) Broad map of the Pacific Ocean plate tectonics showing the “Ring of Fire” (red lines) where the Pacific Plate is colliding with several continental plates, and about ten hot spots (yellow circles). A hot spot is a superheated stationary spot deep in the earth’s mantle resulting in upward movement of volcanic magma and penetration through the oceanic crust of the Pacific Plate and causing submarine volcanic eruptions and formation of island archipelagoes, in the Pacific Crust that have spawned volcanic archipelagos. The East Pacific Rise is at the SE corner of the Pacific where the Pacific and Nazca Plates collide, and about ten named longitudinal fracture zones are to the northwest. (Source of map: National Geographic Society). (b) Marine geological floor of the Pacific Ocean showing vertically exaggerated island groups, seamounts, fracture zones, trenches, and the East Pacific Rise along the SE boundary of the Pacific Plate with the Nazca Plate (Source of map: National Geographic Society).

Pacific Coral Reefs: An Introduction, Figure 11 (Continued)

Marshall, and Gilbert (Tungaru) archipelagos and the two raised islands of Banaba (Ocean Islands) and Nauru, near the Gilberts.

- **Polynesia.** The migrants departed from what is now the Maluku Province of Indonesia about 5,000 years ago and eventually settling in the Pacific about 3,000 years ago at Tonga and Samoa and then slowly moving eastward to what is now the Society Islands in the SE Central Pacific. Then between 1,100 and 600 years ago, a second, broader series of migrations occurred in several waves, beginning with Tahitians and later generations of evolving Polynesian cultural groups who moved:
  1. Westward to what are now known as the Cook, Niue, Tokelau, Tuvalu, New Zealand Islands
  2. Northward to the Marquesas and Hawaiian Islands
  3. Eastward to what are now known as the Tuamotu, Pitcairn, and Easter [Rapa Nui] Islands
  4. Southward to the Austral and Gambier Islands, and then
  5. Northwestward towards the Carolines, Fiji, northern Solomon Islands, and northern Papua New Guinea, including islands previously settled by Melanesians and Micronesians.

Samoans also reached the previously settled Gilbert and Tokelau Islands within the last 800 years. It is also likely

that Polynesians reached South America before the era of European rediscovery (Figure 20). Several island groups (Phoenix, Line) in the central Equatorial Pacific were visited by both Polynesians and Micronesians but were not permanently settled at the time of first European explorers 500 years ago, although some were later settled during the past century of European colonial rule.

### Political history of the Pacific since the European rediscovery

Spanish explorers were the first Europeans to discover and navigate across the Pacific Ocean in the early sixteenth century. Spain was also the first to establish colonies at Guam and several Northern Mariana Islands. Other Spanish, French, and British explorers during the sixteenth to eighteenth centuries were mostly exploring, seeking, or transporting gold, silver, pearls, spices, jewels, silks, and trepang. The French, British, and Americans eventually established colonies and/or developed plantation agriculture, forestry, ranching, or mining on some of the larger islands by the mid-nineteenth century (Fiji, New Caledonia, New Hebrides [Vanuatu], Tahiti, New Zealand, Australia, Hawaii). In 1876, Germany began establishing large colonies in the Pacific including Nauru, Papua New Guinea, Western Samoa, Northern Mariana, Caroline, and Marshall Islands. In turn, this prompted other

**Pacific Coral Reefs: An Introduction, Figure 12** Global projection of the Pacific Ocean showing the major surface currents in the northern and southern hemispheres. Red – warm western ocean currents, blue – cold eastern ocean currents, and yellow – cross-ocean currents at intermediate temperatures that are either warming up or cooling off (Source of base map: D Mapas (2009), Europa Technologies (2009), Tele Atlas (2009), and Google Earth (2009)).

world powers to annex islands or establish colonies in the rest of the strategically important Pacific. Of special importance was mining of guano because of its agricultural value as a fertilizer and ingredient for gunpowder. France and Great Britain established territories in French Polynesia, Wallis and Futuna, New Hebrides [Vanuatu], Solomon Islands, Gilbert Islands, and Ellice [Tuvalu] Islands. The US annexed the Philippines, Hawaii, American Samoa, Guam, Wake Atoll, Midway Atoll, and the Panama Canal Zone between 1898 and 1903, and the US and Great Britain also claimed smaller islands previously mined for guano.

After Germany declared war at the outbreak of World War I (WWI) in Europe in 1914, Japan seized German colonies in the Marshall, Caroline, and Mariana Islands while New Zealand, Australia, and Great Britain took custody of the remaining German possessions after WWI and the defeat of Germany. After 1935, Japan began fortifying its Pacific possessions, and the USA, Great Britain, and Australia claimed and/or fortified additional islands in the Line, Tuvalu [Ellice], Solomon, Gilbert, and Phoenix Islands and Papua New Guinea. After WWII and creation of the United Nations, a dozen inhabited trust territories were designated (Figure 20) with the goal of preparing them

for self rule and democracy; these primarily included inhabited islands claimed, captured, and colonized before and between the two world wars. Most of the Pacific islands are now independent republics or democratically governed territories and protectorates as voted upon and chosen by the resident populations (see Table 1). Only the Kingdom of Tonga has been spared the colonialism experienced by all other Pacific cultures during the past five centuries. The economies of the islands have now shifted to fisheries, tourism, agriculture, ranching, mariculture, mining, and military defense. The emerging island nations also continue to respect their traditional cultures and control of lands and marine areas for subsistence and conservation to maintain valued resources, including coral reefs.

### Status of and threats to Pacific coral reefs

The massive size of the Pacific Ocean combined with low human population densities and high buffering capacity has to date spared most of its coral reefs from the degradation experienced by reefs in the other oceans and seas where human populations are much denser. The largest marine-protected areas (MPAS) in the world are now established in the Pacific including the Great Barrier Reef

**Pacific Coral Reefs: An Introduction, Figure 13** Distribution of low reef islands and atolls and about a dozen raised limestone islands in the central Pacific (Source: Stoddart (1992)).

**Pacific Coral Reefs: An Introduction, Figure 14** Distribution of high limestone islands primarily along in the western Pacific, with many to the west of the solid line. Black circles are Makatea Islands or volcanic islands with substantial Makatea limestone (Source: Stoddart (1992)).

**Pacific Coral Reefs: An Introduction, Figure 16** Coral species richness at Pacific archipelagos showing increasing trends towards the western Pacific and the Coral Triangle. Color legend shows white for lower levels of diversity through increasing shades of yellow, orange, and red for higher levels of diversity. Map after Coral Geographic, J.E.N Veron et al. (2009).

**Pacific Coral Reefs: An Introduction, Figure 17** Color-based coral species richness levels at 70 individual islands and reefs in the Pacific. Color legend follows the same scale as in Figure 16, with white lowest and red highest in species richness per island or reef. Reef codes (in parentheses): A = atoll, B = barrier reef, C = closed atoll, I = volcanic island, L = raised limestone island, R = reef, and S = submerged reef. Explanations for island names, in alphabetical order for both Figures 17 and 18: AIL = Ailinginae (A), ANG = Angaur (I), ARN = Arno (I), AUN = Aunu'u (I), BAB = Babeldaob (B), BAK = Baker (I), BIK = Bikini (A), BIR = Birnie (I), BOK = Bokaak (A), CHU = Chuuk (B), ENE = Enewetak (A), ERI = Erikub (A), FAN = Fanna (I), FFS = French Frigate Shoals (A), FLI = Flint (I), Gardiner Pinnacles (I), Hawai'i (I), HEL = Helen Reef (A), HOW = Howland (I), JAR = Jarvis (I), JEM = Jemo (I), JOH = Johnston (A), KAN = Kanton (A), KAU = Kaua'i (I), KIM = Kimbe Bay (B), KIN = Kingman Reef (R), KIR = Kiritimati (A), KOS = Kosrae (I), KUR = Kure (A), LIS = Lisianski-Neve (A), MAJ = Majuro (A), MAL = Malden (L), MAR = Maro (R), MAU = Maui (I), MER = Merir (I), MID = Midway (A), MIL = Millennium (A), MIN = Minto (R), MOL = Moloka'i (I), NEC = Necker (I), NGE = Ngeruagil-Velasco (R&S), NIH = Nihoa (I), NUK = Nukunonu (A), OAH = O'ahu (I), OFU = Ofu-Olosega Islands (I), OROL = Oroluk (A), ORON = Orona (A), P&H = Pearl and Hermes (A), PAL = Palmyra (A), PEL = Peliliu (I), POH = Pohnpei (B), PUL = Pulo Anna (I), RAIT = Raita Bank (S), RON = Rongerik (A), ROS = Rose (A), SON = Sonsorol (I), STA = Starbuck (L), SWA = Swains (C), TAB = Tabueraan (A), TAK = Taka (A), Ta'u (I), TER = Teraina (I), TOB = Tobi (I), TUT = Tutu'ila (I), VOS = Vostok (L), WAK = Wake (A), WOT = Wotia (A), and YAP = Yap (B). (Source: Maragos and Williams (in preparation)).

**Pacific Coral Reefs: An Introduction, Figure 18** Results of multivariate similarity profile analyses comparing the coral species compositions among the same 70 islands and reefs of Figure 17. Results show 25 statistically distinct clusters among the 70 reefs (green = < 60%, blue = 60–80%, red = > 80% similarity). Locations left unmarked form a “cluster” in isolation (e.g., JOH.). Lines connect spatially separated locations that form an individual cluster (e.g., POH and YAP). Five locations that are extremely spatially separated form an individual cluster, indicated by “+”. Preliminary multivariate analyses indicate that longitude, proximity to the North Equatorial Countercurrent, size of reef, distance to nearest reef, and size of neighboring reefs all may be important contributing factors. Island codes listed in caption for Figure 20 (Source: Maragos and Williams (in preparation)).

of Australia, Northwestern Hawaiian Islands, several northern Line Islands, Phoenix Islands, much of New Caledonia’s reefs, and marine areas around the Mariana Trench. Several more of the northern Marshall Islands and the southern Line Islands may also be formally protected soon as MPAS, and there are hundreds of smaller MPAS now scattered throughout the Pacific.

The major existing impacts to Pacific reefs are sea surface temperature anomalies, tropical cyclones, tsunamis, urban pollution, coastal construction, and over-fishing near population centers, exacerbating coral disease, bleaching and excessive predation by crown-of-thorn sea stars (*Acanthaster*), and localized dominance of invasive species. Additionally there are residual effects of WWII construction of military bases and related battles, and the postwar impacts of the USA, British, and French nuclear testing programs in the Pacific.

### The future of Pacific coral reefs

Despite the generally excellent status of many of its reefs at this time (Riegl and Dodge 2008), Pacific coral reefs

and related islands face an uncertain future. Past development proposals that would have adversely affected Pacific reefs may arise again: a sea-level canal through Central America; use of atolls and islands for garbage disposal, storage of nuclear waste, commercial missile-launching sites, oil transshipment facilities, and desalinization plants. The unauthorized poaching of fish and use of destructive fishing methods is already a major concern, especially near uninhabited islands and reefs where fish stocks are plentiful. Also, incidents of grounded and wrecked fishing vessels on remote reefs are on the rise. Emerging Asian economies and demand for fish are depleting tuna and other commercial fishing stocks in other oceans and East Asian seas, and compelling Pacific nations to enter into unenforceable fishery treaties that support foreign plans to establish fish processing bases throughout the tropical Pacific. During the past two centuries, wooden sailing vessels with poor navigation capabilities avoided remote reefs and islands for fear of crews being wrecked, grounded, stranded, or eaten by sharks. Now, thousands of modern steel-hulled fishing vessels with GPS are plying the Pacific in search of islands, reefs,

**Pacific Coral Reefs: An Introduction, Figure 19** Map showing the migration and settlement patterns of the Pacific islanders throughout Oceania over the past several millennia (Source of map: ORSTOM 1981).

sharks, and other fishing grounds, often far from the watchful eyes of residents and the limited enforcement assets of their governments.

### Responses to global climate change

Sea level, tropical cyclone, and temperature rises and possibly ocean acidification pose as serious threats to reefs worldwide (see entry “*Climate Change and Coral Reefs*”). However, many remote Pacific reefs may harbor greater resilience to these impacts due to the lack of present-day direct anthropogenic impacts. Although sea-level rise may destroy islands and force islanders off low islands and atolls, the reefs themselves may continue to survive and grow upwards. However, endemic and indigenous wildlife (nesting seabirds and sea turtles, resting shorebirds, Hawaiian monk seals) on low uninhabited and undisturbed atolls and reef islands will be most at risk as their island habitats are washed away. Emergency habitat development and translocations may be needed for many species to save them. Many of these islands now have alien rats and cats that prey on smaller ground-nesting seabirds, especially petrels, shearwaters, and terns.

Many undisturbed Pacific reefs would serve as excellent field laboratories to assess the effects of global climate change not complicated by other anthropogenic effects. Appendix A is a listing and catalogue of intact reefs

(1) at the margins in the Pacific, and (2) along the Equator that could serve as excellent field laboratories for climate-change research, spanning the spectrum of Pacific climatic and oceanic habitats.

### Summary and conclusions

The Pacific Ocean is the World’s last true frontier on Earth. We are still in the discovery and inventory phase as to understanding the wealth and diversity of coral reefs and the reef life that inhabits or depends upon them. Pacific reefs remain in excellent condition at this time, although Asian economic expansion and global climate change are now beginning to threaten these coral reefs and their inhabitants. Islanders that dwell on low reef islands and atolls will likely need to be evacuated, while many terrestrial wildlife species on low uninhabited islands may need to be saved from extinction. The nations and cultures within Oceania should consider forming their own federation to protect and care for islanders who will need assistance and new homes, and save island wildlife species threatened with extinction. Some of the key elements of such a federation would be to:

- Promote ecological and climate-change research to better respond to the future
- Research and develop remote surveillance technology to discourage unauthorized fishing and access

**Pacific Coral Reefs: An Introduction, Figure 21** (a) Kure Atoll (2004 image) at the northern tip of the Northwestern Hawaiian Islands, and the northernmost atoll in the Pacific Ocean ( $28^{\circ} 25' N$  Latitude and  $178^{\circ} 20' W$  Longitude). Maximum diameter of atoll is 7 km. Image processed by D. Siciliano. (Source of image: Quickbird Imagery and DigitalGlobe (2009)). (b) Aerial image of Ducie Atoll (December 2004), the most southeastern atoll in the subtropical Pacific ( $24^{\circ} 41' S$  Latitude and  $124^{\circ} 47' W$  Longitude) with a 2 km scale bar. (Source: Google Earth, Europa Technologies, and DigitalGlobe (2009)). (c) Aerial Image of Minami Torishima [Marcus Island], September 2003, the most northwestern low reef island in the Pacific ( $24^{\circ} 17' N$  Latitude and  $153^{\circ} 59' E$  Longitude), with a 1 km scale bar. (Source: Google Earth and DigitalGlobe (2009)). (d) A partial aerial image of Helen Reef, one of the most western atolls in the tropical Pacific ( $2^{\circ} 54' N$  Latitude and  $131^{\circ} 51' E$  Longitude) and showing a 10 km scale bar (Source: Google Earth (2009), and DigitalGlobe (2009)).

- Restore reefs degraded by WWII construction and battles
- Treaties with neighboring developed nations to assist in enforcement of territorial seas and access to remote surveillance technology
- Establish a ocean-wide system of marine protected areas and employment opportunities for islanders to manage, monitor and restore habitats and species, and promote compatible visitation and education
- Negotiate fishery treaties and other foreign development that would be in the best interests of all the peoples and resources of Oceania

### Appendix A: Gallery of coral reefs at the margins and Equator of the Pacific Ocean

The following islands and atolls are a few of the many coral reef formations at the margins of the Pacific Ocean basin, and all are in relatively pristine states and potentially important for various aspects of climate change and ecological research.

- Kure Atoll, North Pacific, northernmost atoll in the Pacific ([Figure 21a](#))
- Clipperton Island, NE Pacific ([Figure 21b](#)), most north-eastern reef in the Pacific

**Pacific Coral Reefs: An Introduction, Figure 22** (a) Google Ocean image of the Haimahera Sea, north of New Guinea where a dozen small and two large islands cross the Equator at 129° 36' E Longitude. (Source: Europa Technologies (2009), Tele Atlas (2009), and Google Earth (2009)). (b) Google Ocean image of the Equator between several islands (Kuria, Aranuka, Abatiku, and Nonouti) in the Southern Gilbert Islands of Kiribati at Longitude 173° 49' E. (Source: Europa Technologies (2009) and Google Earth (2009)). (c) Google Ocean image of the Equator crossing northern Isla Isabela and close to the rest of the Galapagos Islands at 90° 32' W Longitude. (Source: Europa Technologies (2009), Lead Dog Consulting (2009), and Google Earth (2009)). (d) Aerial image, Dec 2007, of Kapingamarangi with a 5 km scale bar, an atoll settled by Polynesians about 600 years ago. The atoll is within 1° N of the Equator at Longitude 154° 46' E, and south of the Pohnpei State of the Caroline Islands (Source: DigitalGlobe (2009) and Google Earth (2009)).

- Ducie Atoll, SE Pacific (Figure 10), most southeastern atoll in the Pacific
- Minami Torishima (Marcus Island), NW Pacific (Figure 21c), most northwestern reef in the Pacific where Japan maintains a weather station, and
- Helen Reef (Figure 21d), one of the westernmost atolls in the Pacific

One island in the eastern border of the Pacific (Isabela in the Galapagos) and a dozen islands in the Haimahera Sea, NW of New Guinea, at the opposite end of the Pacific

support the only reefs crossing the Equator within the Pacific Ocean. Several other reefs in the Northern Phoenix, Southern Gilberts, Southern Lines, and Kapingamarangi Atoll in the Caroline Islands fall within 1° of latitude of the Equator. Some of these islands are uninhabited, many are in healthy condition, and most could serve as important sites for climate-change research.

- Jarvis Island National Wildlife Refuge (NWR), central Line Islands (Figure 15.13, in Maragos et al., 2008)

- Banaba and Nauru Islands, west of the Gilbert Islands (see Figure 9)
- A dozen Haimahera Sea islands, north of New Guinea (Figure 22a)
- Several islands in the southern Gilberts (Figure 22b)
- Isla Isabela in the main Galapagos Islands in the Eastern Pacific (Figure 22c)
- Kapingamarangi Atoll south of the Caroline Islands (Figure 22d)
- Baker Island NWR in the northern Phoenix Islands (Figure 15.11, in Maragos et al., 2008), and
- Howland Island NWR in the northern Phoenix Islands (Figure 15.12, in Maragos et al., 2008).

## PALAEOSOLS

Colin D. Woodroffe  
 University of Wollongong, Wollongong, Australia

## Synonyms

Paleosols; Terra Rossa soils

## Definition

A palaeosol (or paleosol) is, as its name suggests, an old soil. The term is particularly used to describe the reddish layers, also called *terra rossa*, that occur over the surface reef limestones and within fossil dune sequences.

Soils form on subaerial exposures, such as on reef islands, or on the surface of reef limestones when these are exposed at times of lower sea level. Palaeosols, the remnants of former soils, are encountered where the soil has become lithified and has been preserved. The upper surface of reef limestones often has an incomplete cover of these former soils, together with other diagenetic evidence of exposure to terrestrial processes. These formed at times when the carbonates have been emerged, particularly during glaciations. Pleistocene reef limestones are often capped by a reddish brown crust, also called “caliche,” or calcrete, as across many of the islands in the Bahamas. A similar surface is encountered where drill cores intersect the upper surface of buried Pleistocene surfaces, as at discontinuities beneath Eniwetok, Mururoa, and Fangataufa, and on reefs on the Great Barrier Reef. These former soils are marked by micrite and sparry cements, as well as reddish-brown colouration.

On several emergent islands, such as Nauru and Niue, there are extensive deposits of phosphate that are interpreted to have accumulated from the droppings of seabirds, and which is known as guano. Phosphate-rich soils occur on some reef islands where there are presently large numbers of seabirds, and cemented phosphate deposits on Holocene-age islands are similarly considered to be the remnants of soils developed in this manner, lithified, and preserved as palaeosols.

Particularly well-developed palaeosols are associated with carbonate dune deposits. Fossil dunes, termed as aeolianite (or eolianite), are composed of sand-sized carbonate sediments, also known as calcarenite. On large calcarenite islands, such as Bermuda and the islands of

the Bahamas, the separate phases of dune accumulation are bounded by prominent red palaeosols. A lesser interruption in dune accretion is marked by a less well-developed soil horizon known as a protosol, or a hard layer of calcrete.

Palaeosols formed during periods when the dunes were stabilized by vegetation. Despite an early view that the fossil dunes formed during periods of low sea level, such as the last glacial maximum, it is now known from extensive dating on many eolianite islands that most dunes accumulated during sea-level highstands. The clay-rich palaeosols mark those periods during which the sea was lower, the glaciations. Prominent in many palaeosols are fossils of land snails, such as *Cerion* in the case of the Bahamas, and *Placostylus* on Lord Howe Island. Also widespread are the bones of seabirds, as well as rich assemblages of other fossils. Identification and dating of palaeosols and their correlation across islands enables discrimination of the intervening fossil dune formations. These sequences have been particularly effectively mapped and researched on the island of Bermuda.

## PALEOCLIMATE FROM CORALS

---

Helen V. McGregor  
 University of Wollongong, Wollongong, NSW, Australia

## Synonyms

Coral-climate proxies; Coral palaeoclimatology/paleoclimatology; Paleoceanography; Past climates from corals

## Definition

*Coral paleoclimatology* is the use of geochemical records from the skeletons of fossil or modern corals to reconstruct tropical climate variability during the time the coral lived.

## Introduction

Ocean–atmosphere interactions in the tropics have far-reaching consequences for climate variability across the globe. The tropics drive heat transfer to the poles, and tropical inter-annual oscillations such as the El Niño–Southern Oscillation (ENSO) and Indian Ocean dipole (IOD), via atmospheric teleconnections, affect rainfall patterns and climate conditions in areas far beyond the tropics (Ropelewski and Halpert, 1987), causing major socio-economic impacts. Monitoring efforts have focused on improving observations and understanding of tropical climate variability, with the view to refining modeling of the tropical oceans and atmosphere. Despite these efforts, most instrumental records span only the past few decades and do not capture the full range of tropical climate variability, limiting our ability to model future changes. Coral paleoclimatology offers the prospect to extend instrumental records of tropical climate variability and can provide unique insights into tropical ocean–atmosphere interactions.

Long-lived, massive corals record climate changes in the geochemistry of their skeletons. As corals grow, they deposit an aragonitic (calcium carbonate) skeleton, usually as one high and low density band per year, visible by x-ray of the coral skeleton (Barnes and Lough, 1993). Incorporated in the coral skeletons are varying proportions of geochemical elements, depending on the prevailing environmental and climatic conditions in the ambient seawater in which the corals live, and on the coral's own physiology (see “[Stable Isotopes and Trace Elements](#)”). The geochemical, or the so-called “proxy,” records derived from the coral skeletons can be measured at sub-annual resolution and can be empirically related to a given climate parameter (e.g., [Figure 1](#)). Widely used coral proxies include the ratio of strontium to calcium (Sr/Ca), a proxy for sea surface temperature (SST), and the coral oxygen isotope ratio ( $\delta^{18}\text{O}$ ). The coral  $\delta^{18}\text{O}$  is a function of SST and the  $\delta^{18}\text{O}$  of seawater, where the  $\delta^{18}\text{O}$  of seawater correlates with changes in sea surface salinity (SSS), which in turn may respond to changes in rainfall. Using the Sr/Ca SST proxy, the SST component of the coral  $\delta^{18}\text{O}$  signal can be removed leaving the oxygen isotope residual ( $\Delta\delta^{18}\text{O}$ ) a SSS-only proxy (McCulloch et al., 1994; Gagan et al., 1998; Gagan et al., 2000). With the most commonly used coral genus *Porites* often living for a century or more, measurement of the coral skeletal geochemistry can provide quantitative, seasonally resolved, century-length records of climate variability for the time the coral lived.

## Reconstructing climate records from corals

*General approach.* There are two main approaches to reconstructing past climates from corals using modern or

**Paleoclimate from Corals, Figure 1** IOD climate anomalies. (a) SST anomalies during November of the 1997 IOD event (Reynolds and Smith, 1994), when anomalous cooling in the east and warming in the west produced a reversal of the equatorial SST gradient across the Indian Ocean. Boxes mark the eastern and western sectors used to define the dipole mode index (Saji et al., 1999), and the white circle shows the location of the Mentawai Islands. (b) In the Mentawai Islands the strong IOD events of 1994 and 1997 were characterized by cool SST anomalies (black curve; Saji et al., 1999) and drought (gray bars; Xie and Arkin, 1996). These distinct IOD SST and rainfall anomalies are preserved, respectively, in coral Sr/Ca SST (red circles and curve) and  $\Delta\delta^{18}\text{O}$  (blue circles and curve) anomalies (Gagan et al., 1998). Coral time series between July 1993 and February 1997 are based on the average of two coral records, with error bars showing the difference between the coral records for each monthly data point. (Reprinted by permission from Abram et al. [2007].)

fossil corals. The most common approach is to collect a core from a live coral on a reef. The chronology is provided from the coral density growth bands and/or the seasonal cycle recorded in the coral geochemical records. Annual coral density bands can be counted; beginning at the tissue layer at the uppermost surface of the coral, the paired high and low density bands, revealed by x-ray of the coral, are counted back in time. Coral density bands are not always well defined, so alternatively the annual peaks or troughs in the coral geochemical climate proxies can themselves be counted. Using either method, or a combination of the two, it may be possible to count back several centuries with errors of 1 or 2 years (Lough and Barnes, 1997; Guilderson and Schrag, 1999; Hendy et al., 2002; Hendy et al., 2003). The advantage of using a modern coral for climate reconstruction is that the start age is known and the coral geochemical proxies can be

directly calibrated against climate parameters as measured in the instrumental records increasing the robustness of the reconstruction. In addition, replicate coral cores can be taken from different coral heads from the same reef, enhancing reproducibility. The disadvantage is that the reconstructed record is limited by the length of time the coral lived, usually no longer than a few centuries. Dating errors may increase further back in time. There are now significant numbers of modern coral records extending back several centuries from the present day from various locations throughout the tropics such that the records are being combined to examine the climate connectivity of the tropical oceans (Kaplan et al., 1998; Evans et al., 2000; Hendy et al., 2002; Charles et al., 2003; Wilson et al., 2006).

An emerging alternative approach is to use well-preserved fossil corals to reconstruct climate further back

**Paleoclimate from Corals, Figure 2** Fossil *Porites* sp. coral from Muschu Island, Papua New Guinea. The coral, once living underwater on the reef, has been uplifted by tectonic activity and is now preserved as an isolated coral head within the intertidal zone, and is exposed at low tide. Note the concentric growth bands in this coral and that the top of the coral has been planed flat.

in time (Figure 2). The age of the fossil coral can be precisely determined using radiocarbon or U-series dating, and the proxy climate record from the coral skeleton provides a “snapshot” of past variations (e.g., Beck et al., 1997; Gagan et al., 1998; Tudhope et al., 2001; Woodroffe et al., 2003; Corrège et al., 2004; Felis et al., 2004; McGregor and Gagan, 2004; Abram et al., 2007). It is also essential to analyze a modern coral that overlaps instrumental record to quantify the coral geochemistry–climate parameter relationship since the same climate proxies are used for the fossil and modern corals. In this case, the modern records for calibration need not extend back several centuries. The major advantage of using fossil corals is that it is possible to look at climate variations further back in time when the climate boundary conditions were different from today, giving a perspective on the range of possible, natural climate modes. The disadvantage of using fossil coral proxy records is that they are almost inevitably disjointed. However, an exciting new development has been to use high-precision U-series dating of multiple fossil coral and look for age overlaps (Cobb et al., 2003; Zhao et al., 2009). Age dating errors are typically  $\pm 0.5\%$ , equivalent to less than a decade for Holocene-aged corals, and where individual fossil corals overlap in age their proxy records can be pieced together, where the climate “wiggles” from each individual coral are matched, to produce a longer record (Cobb et al., 2003).

**Coral-climate signals and reproducibility.** For both fossil and modern coral studies, it is essential to establish the climate factors controlling the signal at a given location, quantify this relationship, and determining the magnitude of associated errors. For example, the commonly used  $\delta^{18}\text{O}$  proxy reflects changes in both SST and SSS. However at some locations, such as in PNG in the western tropical Pacific SSS changes dominate the signal (Tudhope et al.,

2001; McGregor, 2004), whereas at locations such as the central Pacific SST exerts the major control (Evans et al., 2000; Woodroffe and Gagan, 2000). In addition, the aim for coral paleoclimatology is often to be able to use the coral proxy record from a single location to infer regional climate variability. Thus, the climate factors that control the coral proxy climate signal must be quantifiably related to regional climate variations (Guilderson and Schrag, 1999). Some locations appear to be “nodes” for particular tropical climate oscillations (e.g., ENSO or the North Atlantic Oscillation), and coral records from these locations can be representative of climate variability over very large spatial areas. One example of this is where coral-climate records from Kiritimati Island were used to construct a coral-C INDEX, equivalent to the NINO3.4 Index used to define ENSO events (Evans et al., 1998). From this point of view, corals from well-flushed reef settings are preferred. For in situ fossil corals it is usually possible to establish the paleo-reef morphology; however, for transported corals (dislodged either by storm activity or post-uplift erosion) establishing provenance is almost impossible (Cobb et al., 2009).

Several studies have suggested that proxy climate signals from corals living on the same reef may show higher between-coral (inter-reef) differences than that expected from climate variability alone (Guilderson and Schrag, 1999; Linsley et al., 1999; Cohen et al., 2002; Felis et al., 2003). The origins of these offsets are not well understood, and, in addition, there are studies that suggest minimal between-coral offsets (Gagan et al., 1998; Hendy et al., 2002; Stephans et al., 2004). But between-coral differences appear to affect the coral oxygen isotope ratios more than Sr/Ca. Coral growth form, growth rate, reef setting, and diagenesis have all been suggested as possible causes of offsets (Cobb et al., 2009). Corals can also show within-coral variations (McConnaughey, 1989; de Villiers et al., 1995; Alibert and McCulloch, 1997; Cohen and Hart, 1997). Regardless of the origin and magnitude of between-coral and within-coral offsets, reproducing proxy climate signals from the same location, using at least two corals, will reduce uncertainty and quantify errors in climate reconstructions from both modern and fossil corals (Lough, 2004; Stephans et al., 2004; Abram et al., 2009).

**Diagenesis.** An underlying assumption in the use of corals to reconstruct climate is that the corals are pristine, that is, that original coralline aragonite is preserved. However, coral skeletons are susceptible to a process known as diagenesis. Diagenesis is the precipitation of secondary aragonite or calcite in skeletal voids, or the replacement of skeletal aragonite, usually with calcite. If even a small amount of diagenetic material is included in a sample, then the resulting climate reconstruction may be rendered inaccurate. This is because isotopes and trace elements are exchanged and removed during the diagenetic transformation, changing the geochemistry of the coralline matrix. For example, secondary calcite can lead to “warm” SST artefacts (SST appears warmer than was the case), particularly in Sr/Ca SST reconstructions, of  $1^\circ\text{C}$  or more

(McGregor and Gagan, 2003). Secondary aragonite, typical for early marine diagenesis of modern corals, causes considerable alteration of coral geochemistry and creates “cool” SST artefacts (Bar-Matthews et al., 1993; Enmar et al., 2000; Müller et al., 2001; Lazar et al., 2004; Müller et al., 2004; Allison et al., 2007). Dissolution was shown to create “cool” anomalies in a range of trace element SST proxies (Hendy et al., 2007). Diagenesis has been observed in living corals and corals just a few decades old (Enmar et al., 2000; Müller et al., 2001; Hendy et al., 2007; Nothdurft et al., 2007); however, fossil corals are more susceptible to diagenetic processes as they are exposed to seawater, sea spray, rainfall, and/or groundwater for centuries to millennia or longer.

Numerous studies have called for screening for diagenesis in modern and fossil corals to become standard procedure (McGregor and Gagan, 2003; Gagan et al., 2004; Quinn and Taylor, 2006; Allison et al., 2007; Hendy et al., 2007; Cobb et al., 2009). Diagenesis that produces an addition of ~10% or more secondary material to the skeletal bulk density can be detected in coral density profiles, X-radiographs, and UV luminescence photos (Hendy et al., 2007). However, just 1% calcite diagenesis would alter the coral climate signal (McGregor and Gagan, 2003). X-ray diffraction (XRD) has been the most commonly used diagenesis screening method in coral paleoclimate studies. However, XRD detects secondary calcite, not secondary aragonite or dissolution, and the XRD detection limit is effective down to around the 1% calcite (McGregor and Gagan, 2003; Allison et al., 2007). For lower levels of diagenesis, thin section is proving a highly effective means of screening samples for all types of diagenesis (McGregor and Gagan, 2003; McGregor and Abram, 2008; Cobb et al., 2009). One thin section per 20–30 years of coral growth is recommended (Cobb et al., 2009) and a guide has been developed to assist coral paleoclimatologists in screening using thin sections (McGregor and Abram, 2008). Scanning electron microscopy (SEM) is also a highly effective tool for diagenetic screening (Nothdurft et al., 2007).

### Coral paleoclimate records

One of the major strengths of corals as paleoclimate archives is their ability to record monthly or finer resolution (e.g., weekly) climate information. This level of resolution means corals are ideally suited to investigating inter-annual climate phenomena, such as the El Niño–Southern Oscillation and the Indian Ocean Dipole. Approximately 90 coral proxy records based on corals that were alive at the time of collection have been published, with around 30 of those extending from the late twentieth century back prior to 1900 (Jones et al., 2009). These longer coral records are able to provide a wealth of information on multidecadal to centennial timescale variability. At least one coral record exists from every tropical ocean, with the vast majority of records from the tropical Pacific. There are significantly fewer records from

older fossil corals. Coral paleoclimatology has made a significant contribution to understand a number of facets of tropical climate variability and a snapshot of these contributions will be discussed in the following sections.

### Interannual and multi-decadal variability in the tropical Pacific: variations past and present

A key focus of coral paleoclimate research has been in extending records of the El Niño–Southern Oscillation system. ENSO, with its origins in the equatorial Pacific, is the largest source of interannual climate variability across the planet. It is a coupled climate system between the atmosphere and the ocean, and it oscillates irregularly on a timescale of 2–7 years. The average state of the equatorial Pacific Ocean involves strong easterly trade winds pushing warm water to the west, which then brings (upwells) cool subsurface water in the east. This sea surface temperature gradient then reinforces the easterly winds. A La Niña event is an enhancement of the average state, where the easterly winds and temperature gradient strengthen. In an El Niño event, the easterly winds slacken and reduce the ocean temperature gradient, allowing warm water to flow back to the central and eastern Pacific. Atmospheric convection and precipitation follows the warmest water, and in an El Niño, above average rainfall is deposited over the central Pacific. El Niño events have become stronger and more frequent since the mid-1970s (McPhaden et al., 2006). However, there is debate about whether strengthened El Niño is a result of global warming or whether the 1970s intensification resulted from a decadal or longer-term cycle of ENSO variability (Fedorov and Philander, 2000; Cane, 2005; McPhaden et al., 2006). The relatively short instrumental record does not give a complete picture of ENSO behavior, and models are unable to simulate ENSO fully, limiting our ability to predict future ENSO scenarios.

Corals from optimal locations across the equatorial Pacific are able to capture the SST and rainfall/SSS variations that result from ENSO oscillations (Cole et al., 1993; Dunbar et al., 1994; Evans et al., 1998; Urban et al., 2000), and have complemented and extended instrumental records of ENSO variability. Spectral analysis of one of the earliest published coral  $\delta^{18}\text{O}$  records, that from Tarawa Atoll, western Pacific, showed changing dominance of seasonal and interannual variability through the twentieth century, suggesting a change in the ENSO “pulse” (Cole et al., 1993). Further analysis of the Tarawa  $\delta^{18}\text{O}$  record and comparison with a 155 year  $\delta^{18}\text{O}$  record from Maiana Atoll, just south of Tarawa, revealed, among other things, that the 1976 shift in ENSO variability coincided with changes in the mean background climate of the tropical Pacific, with the ENSO period shifting from 2.9 to 4 years across the 1976 change (Urban et al., 2000). The record also revealed that during the late nineteenth century, ENSO cycles lasted 10–15 years. These results are significant because they show that the length of the ENSO cycle varies with small changes in tropical climate.

Furthermore, the results suggest that there is substantial natural variability in ENSO, but that the most recent period may be unique in that the changes in the mean climate due to anthropogenic greenhouse gases may also influence ENSO (Dunbar, 2000).

The network of coral-climate records from across the Pacific, although still sparse, does appear to capture large-scale, multi-decadal climate variance, and in combination with coral records from other ocean basins, is revealing ocean-atmosphere connections right across the tropics. Consensus is emerging for significant decadal variability in tropical Pacific SSTs at the 9–14 year period (Cobb and Charles, 2001; Holland et al., 2007; Ault et al., 2009). The decadal variability displays an ENSO-like spatial and temporal pattern suggesting that the Pacific decadal-scale variance is directly related to ENSO (Urban et al., 2000; Holland et al., 2007; Ault et al., 2009). Decadal-scale variability appears to be stronger in the late nineteenth century, and analysis based on only twentieth century records may underestimate decadal-scale variability (Ault et al., 2009). Synthesis of coral SST records spanning the whole tropics suggests that the late twentieth century is the warmest period for the past 250 years, which can be explained by the increase in anthropogenic greenhouse gases in the atmosphere (Wilson et al., 2006). A consistent antiphased correlation between the South Pacific Convergence Zone, a low pressure trough extending from around the Solomon Islands to French Polynesia, and the decadal variability in the central equatorial Pacific has been documented back to 1650 AD (Linsley et al., 2008). At the decadal-scale the Atlantic Ocean may be directly influenced by SST anomalies in the central tropical Pacific (Cobb and Charles, 2001), and central equatorial Pacific SSTs also correlate on a variety of timescales with Indian Ocean coral oxygen isotope records, suggesting a decadal-scale connection between these ocean basins (Cobb and Charles, 2001; Charles et al., 2003).

The longest, continuous coral proxy record published to date, based on eight coral cores from the Great Barrier Reef (GBR), sampled at 5-yearly resolution and totaling 420-years from present back to 1565 AD, showed that corals can also record centennial-scale shifts in tropical climate (Hendy et al., 2002). This study was unique in its approach in that it combined records in a similar manner to the approach used in tree-ring studies to extract the robust “common signal” of low-frequency SST and SSS variability in the records. The resulting common GBR SSS anomaly record showed increased salinity between 1565 and 1870, around the time of the Little Ice Age (LIA) in the northern Hemisphere (Hendy et al., 2002). The SST anomaly results, along with other long records from the tropical Pacific, suggest a stronger latitudinal temperature gradient during the LIA, enhancing wind-driven evaporation, giving rise to the high salinity anomalies. The authors suggest that the high evaporation equated to a net export of moisture from the tropics contributing to glacial advance during the LIA (Hendy et al., 2002).

Also, drawing on approaches adapted for tree-ring studies, Cobb et al. (2003) pieced together numerous fossil and modern corals from ENSO-sensitive Palmyra Atoll, central Pacific, to give the first picture of ENSO variability for the past millennium. Their landmark reconstruction was based on dislodged coral heads deposited on Palmyra during storms events. The corals were precisely dated by the U-Th method to identify periods of overlap, and then the monthly resolved  $\delta^{18}\text{O}$  records were “wiggle matched” together. In total, this resulted in 430 years of monthly resolved record, for five intervals across the past millennium. The record showed a surprising degree of variability in ENSO strength, independent of changes in solar or volcanic forcing. In addition, ENSO strength does not appear to relate to changes in Northern Hemisphere climatic periods such as the Little Ice Age or Medieval Warm Period (Cobb et al., 2003). ENSO strength seemingly switches modes in a matter of decades, and the late twentieth century ENSO, although strong, is not unprecedented over the length of the record (Cobb et al., 2003). The results suggest that ENSO can change its character on its own, and in future, may shift with or without an additional push from anthropogenic greenhouse gases (Cobb et al., 2003; Tudhope and Collins, 2003). This presents a challenge for modeling future ENSO behavior, and testing global climate models against past ENSO variability provides a means to refine and improve these models.

Coral paleoclimate reconstructions have been instrumental in understanding the origin and long-term evolution of ENSO (Hughen et al., 1999; Corrège et al., 2000; Tudhope et al., 2001; Woodroffe et al., 2003; Kilbourne et al., 2004; McGregor and Gagan, 2004; Sun et al., 2005). A major discovery from Indonesian and Papua New Guinea (PNG) fossil corals has been that ENSO has been a component of the tropical climate system for at least 130,000 years (Hughen et al., 1999; Tudhope et al., 2001), and has varied significantly in strength through glacial and interglacial cycles (Tudhope et al., 2001). Tudhope et al. (2001) proposed that ENSO strength varied as a result of changes in tropical Pacific seasonality related to the Earth’s orbital cycles (orbital forcing) plus dampening of ENSO strength during glacials. Further work on coral from PNG, and additional coral records from the central Pacific, are providing a more detailed picture of the evolution of ENSO for the most recent Holocene period (10,000 years ago to present; Corrège et al., 2000; Tudhope et al., 2001; Woodroffe et al., 2003; Gagan et al., 2004; McGregor and Gagan, 2004; Sun et al., 2005). These studies suggest that ENSO was less active compared to today, although still present, and may have been more active around 2,000 years ago.

A key component of ENSO and the tropical Pacific climate system is the Indo-Pacific Warm Pool (IPWP). The IPWP is the warmest body of ocean water in the world having an average temperature of  $>28^{\circ}\text{C}$ , and coupled ocean-atmosphere interactions in the IPWP are not only thought to trigger El Niño events, but also deliver large

amounts of heat to the atmosphere via the global atmospheric Hadley-Circulation (Webster, 1994). Much coral evidence for the evolution of ENSO originates from the IPWP and coral data has also provided important information on the long-term climate variability of the warm pool. Sea surface temperature estimates, based on corals from Vanuatu, PNG, GBR, and Indonesia and utilising a revised coral Sr/Ca SST calibration, suggest that the early Holocene IPWP was  $\sim 1\text{--}3^\circ\text{C}$  cooler than present (Gagan et al., 2004 and references therein). Temperatures had reached modern values by  $\sim 8.5$  ka, in general agreement with planktonic foraminifera Mg/Ca and alkenone SST estimates, and mid-Holocene SSTs were  $0.5\text{--}1^\circ\text{C}$  warmer than present (Gagan et al., 2004). A more detailed picture of IPWP SST variations, based on 48 fossil corals from Indonesia and PNG, suggested that the southern margin of the IPWP cooled and warmed periodically through the mid-Holocene, associated with an expansion and contraction of the warm pool as the Asian summer monsoon weakened and strengthened, respectively, and points to the fundamental importance of the warm pool in propagating climate change (Abram et al., 2009).

### Interannual modes in the Atlantic and Indian Ocean

Understanding the influence of the tropical Pacific and ENSO on the Indian Ocean has been recognised as an important issue and corals have played a role in better characterising the interactions. For the past few decades, SSTs in the Indian Ocean have been associated with ENSO and the Asian monsoon via complex multi-feedbacks (Webster et al., 1998). As with the tropical Pacific, however, a major limit in understanding climate variability in the tropical Indian Ocean, and the Indian, East African, and southeast Asian monsoons, on which millions of people are dependent for life-giving rain, has been the absence of records of more than a few decades in length. Multi-century coral oxygen isotope records from the central and western Indian Ocean however, reveal a clear ENSO teleconnection, whereby during El Niño events western Indian Ocean SSTs are warmer (Charles et al., 1997; Cole et al., 2000; Zinke et al., 2005; Pfeiffer and Dullo, 2006). The western Indian Ocean SSTs also display decadal-scale ENSO-like variability (Cole et al., 2000; Pfeiffer and Dullo, 2006), which may be linked to the Pacific decadal oscillation (Crueger et al., 2009).

Although there may be a generally consistent teleconnection between the western Indian Ocean and ENSO, new perspectives from coral records from the eastern Indian Ocean show a changing ENSO–Indian Ocean–monsoon interaction, with potentially negative consequences for SE Asian rainfall under global warming scenarios (Abram et al., 2007). Recently identified IOD events are defined by a reversal of the equatorial Indian Ocean east–west SST gradient and zonal winds from their mean climatological state (Saji et al., 1999; Figure 1),

resulting in drought for western Indonesia and southern Australia (Overpeck and Cole, 2007). IOD events were reconstructed back to 1846 using a suite of corals from the eastern and western Indian Ocean (Abram et al., 2009). The coral IOD index showed an increase in the strength and frequency of IOD events through the twentieth century (Figure 1). The results also showed that despite the historical influence of ENSO in triggering IOD events, the twentieth century IOD intensification was a direct result of IOD–monsoon feedbacks, with consequences for rainfall distribution (Abram et al., 2009).

Coral reconstructions of Holocene IOD events have likewise revealed changes in the IOD–monsoon–ENSO relationship over time (Abram et al., 2007). The results are significant, their strength being that they provide information on monthly scale timing and duration of individual IOD events (Figure 1), and show that  $\sim 6,500$  years ago IOD SST cooling lasted 5 months, up from 3 months for the present day. They also reveal that long-duration IOD events result in drought peaking later in the calendar year than for the present day, coinciding with what would normally be the maximum monsoon rainfall in western Indonesia. The mid-Holocene enhanced IOD cooling and drying is thought to result from strengthened Asian monsoon, and future Asian monsoon–IOD strength may extend drought through Australasia (Abram et al., 2007).

Coral records are making a significant contribution to our understanding of the Atlantic Multidecadal Oscillation (AMO), hurricane activity, and the North Atlantic Oscillation/Arctic Oscillation (NAO/AO). The AMO is a decadal- to multidecadal-scale variation in SSTs across the Atlantic and may be related to hurricane activity in the northern tropical Atlantic (Goldenberg et al., 2001). A 440-year growth rate SST reconstruction from the Bahamas suggests that multidecadal variability may only be significant after 1730, limiting the accuracy of decadal climate forecasts (Saenger et al., 2009). In a related study, luminescence lines from Caribbean corals were used in combination with a marine sediment core proxy record to investigate hurricane frequency, vertical wind shear, SST, and the AMO for the past 270 years (Nyberg et al., 2007). The results suggest that vertical wind shear is more important than SST in controlling hurricane frequency, and controversially, that increased hurricane frequency since 1995 is not unusual compared to other periods of high hurricane activity in the record (Elsner, 2007; Nyberg et al., 2007; Neu, 2008; Nyberg et al., 2008).

Coral records, particularly those from fossil corals, have made key inroads into our understanding of the NAO/AO. The NAO/AO is the dominant interannual atmospheric mode in the North Atlantic influencing the climate of much of Europe via its modulation of the strength of the subpolar westerlies (Hurrell, 1995; Thompson and Wallace, 2001). Oxygen isotopes in corals from the northern Red Sea reflect the influence of the NAO/AO and ENSO on the climate of the region (Felis et al., 2000). Sr/Ca SST records from 125,000 year old fossil corals show increased temperature seasonality

(Felis et al., 2004). In an innovative approach, combining the seasonal-resolution coral data with coupled atmosphere–ocean model simulations, the results suggest that a more positive NAO/AO operated 125,000 years ago contributing to the increased seasonality in the Red Sea coral record, as a response to insolation changes from differences in Earth's orbital configuration at that time (Felis et al., 2004). Such studies help to disentangle natural climate variability and will help us better understand the response of interannual climate oscillations to anthropogenic greenhouse warming.

## Summary

Corals are proving an invaluable source of quantitative data on past climate variability across the tropical oceans, and over a range of timescales from seasonal, interannual, decadal to centennial and millennial. Community wide efforts to extract records from undersampled time periods, such as the LGM and deglaciation (Expedition 310 Scientists, 2006; Webster et al., 2009), and locations, and further integration of coral data and climate model output will continue to see coral paleoclimatology contribute to understanding natural climate variability.

## PATCH REEFS: LIDAR MORPHOMETRIC ANALYSIS

---

John C. Brock<sup>1</sup>, Monica Palaseanu-Lovejoy<sup>2</sup>

<sup>1</sup>U.S. Geological Survey, Reston, VA, USA

<sup>2</sup>U.S. Geological Survey, St. Petersburg, FL, USA

## Setting

Alina Reef is one of several thousand patch reefs that lie across the shallow carbonate platform seaward of Hawk Channel off the northern Florida Keys. The site is near the northern latitudinal fringe of the late Holocene western Atlantic coral reef distribution ([Figure 1](#)). The area is covered by calcareous sand and discontinuous *Thalassia testudinum* seagrass meadows and is studded with numerous scattered Holocene patch reefs. Most of the patch reefs are found in water depths of 2–9 m, are subcircular, elliptical, or irregular in plan view, and range up to about 8 m in vertical relief and 700 m in width. Coring has demonstrated thicknesses of 4.5–6 m and has revealed frameworks built by large, massive head corals.

## Lidar surveys

In August 2002, the Experimental Advanced Airborne Research Lidar (EAARL) system was used by NASA and the U.S. Geological Survey to survey the submarine topography of the broad swath of the reef tract seaward of Elliot Key and within Biscayne National Park ([Figure 1](#)). The NASA – USGS Airborne Lidar Processing System (ALPS) was used to interpret the EAARL laser soundings to create a spot-elevation data set that was subsequently subjected to triangulation and gridding to create a digital-elevation model (DEM) at 1-m cell resolution. Next, a 1-m-resolution slope map was constructed from the lidar-derived DEM based upon

**Patch Reefs: Lidar Morphometric Analysis, Figure 1** The northern Florida Keys reef tract depicted on a QuickBird satellite image.

the average maximum method (Burrough and McDonell, 1998). Lastly, a lidar-rugosity mapping procedure was applied to produce a 1-m-resolution digital rugosity map for the study area (Brock et al., 2006).

### Morphometric analysis

The results of the lidar morphometric analysis at Alina Reef are shown in Figure 2. Alina Reef is depicted on the color-coded digital-elevation map (DEM) as the

**Patch Reefs: Lidar Morphometric Analysis, Figure 2** A subregion of the 1-m-resolution lidar-based (a) topographic, (b) slope, and (c) rugosity maps that were used to define patch-reef boundaries and morphometric attributes. *Black polygons* depict boundaries of the full patch reef, *blue polygons* delimit patch-reef tops, and the area between these polygons on a given reef represents the patch-reef rim.

largest of several surrounding patch reefs at the approximate center of a small subarea of the total region mapped by the EAARL (Figure 2a). The black dots signify the volumetric center points of the patch reefs, one example of the morphological metrics that may be obtained through quantitative analysis of the lidar DEM.

An extensive morphometric analysis across the entire EAARL survey region revealed two morphologically different populations of patch reefs associated with two distinct depth intervals. Alina Reef is an excellent example of an identified group of shallow patch reefs that are generally much broader and flatter than the deeper population. Compared to the shallow reefs, the deep reefs were smaller in area and volume and showed no trend in topographic complexity relative to water depth. The fundamentally different morphologies of the shallow and deep reefs can be clearly seen on the slope map, (Figure 2b) which depicts a small steep-sided deep reef immediately adjacent and to the east of Alina Reef. The slope map also reveals scattered small rubble piles just off the western flanks of several reefs that may stem from the frequent hurricane crossings that impact the northern reef tract.

The roughly 200 m  $\times$  300 m region around Alina Reef mainly contains reefs that are members of the shallow-reef population, revealed by the lidar to be, in comparison to the deep-reef group, more variable in area and volume. Moreover, lidar revealed that reefs in the shallow population became flatter and less topographically complex with decreasing water depth.

The more uniform knoll-like morphology of the deep reefs is consistent with steady and relatively rapidly rising early Holocene sea level that may have restricted the lateral growth of reefs. The morphology of shallow “pancake-shaped” reefs (Figure 3) at the highest platform elevations may have been produced by cycles of growth and erosion driven by fluctuating sea level during the late Holocene (Balsillie and Donoghue, 2004). Although the ultimate cause for the morphometric depth trends sensed by lidar remains speculative, these interpretations are compatible with a recent eustatic sea-level curve that hindcasts fluctuating late Holocene sea level (Siddall et al., 2003). It is thus suggested that the morphological differences revealed by lidar represent two stages of reef accretion that occurred during different sea-level conditions.

**Patch Reefs: Lidar Morphometric Analysis, Figure 3** Oblique perspective topographic depiction of Alina Reef, a shallow patch reef that exhibits the characteristic “pancake” morphology of the shallow patch-reef population in the northern Florida Keys reef tract.

## Summary

Apart from providing evidence for oscillating late Holocene sea level, lidar mapping provided new information on regional reef ecology and benthic community structure. Previous work has shown that many patch reefs in Biscayne Bay are composites of several characteristic zones, namely (a) massive boulder-coral colony clusters, (b) a zone of scattered massive corals with abundant octocorals, and (c) peripheral rubble zones (Ginsburg et al., 2001). The cluster zones occur at the patch-reef margins and are mainly composed of 1–5 m-diameter coalesced colonies of *Montastraea annularis* and *Montastraea faveolata*, along with fewer *Siderastrea siderea* and *Colpophyllia natans* heads. The octocoral zone is basically a hard ground community with areas that are dominated by coral rubble and carbonate sand. The tropical storms and hurricanes that frequently track across the northern reef tract have been implicated in the formation of the rubble aprons that occur at the peripheries of many patch reefs and can readily be identified on the lidar-based slope map (Brock et al., 2006) (Figure 2b).

Analysis of dense lidar-elevation soundings can also yield spatially continuous maps of coral reef topographic complexity, or rugosity. A lidar-based rugosity map (Figure 2c) for the Alina Reef region confirms previous work that established that the known characteristic zonation of Biscayne Bay patch reefs can be sensed remotely and mapped by the EAARL system (Brock et al., 2006). The high-rugosity flanks of Alina Reef and neighboring reefs generally correspond to cluster zones of live or degraded massive boulder-coral colony clusters, or derivative rubble piles. The mixed, low-rugosity upper platforms of these reefs were identified by field observations to represent octocoral zones. In summary, the EAARL lidar reef-mapping test conducted across a portion of the northern Florida Keys reef tract, and the sample presented here, demonstrated that lidar mapping can provide new and valuable information to reef-resource managers, carbonate geologists, and coral reef ecologists.

## PERMIAN CAPITAN REEF SYSTEM

---

Rachel Wood  
 University of Edinburgh, Edinburgh, UK

The Permian Capitan Reef system (275–255 Myr), as exposed in the Guadalupe and Delaware Mountains of the Delaware Basin in New Mexico and west Texas, presents some of the finest outcrops of ancient reef and associated rocks known. Ochoan evaporites, infilled the Delaware Basin preventing extensive erosional modification and structural deformation, so preserving an entire depositional system from the back-reef across the reef margin to the deep basin.

The Delaware Basin was situated close to the western margin of Pangaea, about 10° north of the palaeo-equator and was subjected to subsidence resulting in the accumulation of between 2,100 and 4,200 m of clastic, carbonate, and evaporite strata; 1,000 m alone was deposited during Guadalupian times.

The depositional system can be broadly divided into back-reef, shelf margin, reef-slope and basin sediments. Leonardian and early Guadalupian strata show shelf-to-basin ramp sequences, but these later evolved into a rimmed shelf where the margin was poised nearly 600 m above the basin floor. Topography was further enhanced by reciprocal sedimentation where considerable thicknesses of carbonates were deposited on the shelf area during transgressions and highstands, and clastic material accumulated in the basins during lowstands.

Cyclic sedimentation is widespread in the Permian Basin and operated on many frequencies. Eustatic cycles of roughly a million years or less were superimposed on an apparently long-term drop in sea level throughout late Permian time.

The Capitan reef shows a high biodiversity and is the main Guadalupian carbonate-producing facies, forming a clearly defined, largely continuous margin which surrounds the Delaware Basin. Many different reef-building communities have been documented, including various calcareous sponge-bryozoan assemblages, and phylloid algae (Newell et al., 1953). Some have re-interpreted the previously described reef framework as having lived within cavities (Wood et al., 1996). Many organisms, commonly still found in living position, are often encrusted by possible red or blue-green algae, particularly *Archaeolithoporella* as well as microbialite, which almost certainly represents secondary growth during burial (Figure 1). In addition to framework and encrusting

**Permian Capitan Reef System, Figure 1** Reconstruction of bryozoan-sponge community, Permian Capitan Reef, USA (courtesy J. Sibbick); 1. Frondose bryozoans, 2. organisms, the reefs contain diverse echinoderms, bryozoans, brachiopods, molluscs, ostracodes, scarce solitary corals and trilobites. On the shelfward side of the reef, sponge-algal rubble passes into *Tubiphytes* thickets, and *Mizzia* and *Macroporella* green algal grainstones with bellerophont gastropods.

Late Guadalupian reefs and near-back-reef grainstones are filled with large volumes of syndepositional marine cements (Mazzullo and Cys, 1977). Many reef cavities were rapidly filled with massive botryoids and radial-fibrous cements, partly intergrown with *Archaeolithoporella* and internal sediment.

High rates of biological productivity produced more carbonate than could be accommodated given limited rates of subsidence and, excess material was transported into back-reef and particularly fore-reef environments. As a result, the Capitan reef shows considerable seaward progradation, varying from 10 km on the stable western margin of the Delaware Basin to 3 km on the more rapidly subsiding eastern margin (Ward et al., 1986).

The rapid rates of syndepositional cementation of the reef facies combined with progradation over largely unconsolidated and compactable debris, led to extensive syndepositional fracturing of the cemented reef slabs and differential subsidence of the reef complex as a whole (Saller, 1996).

## PERSIAN/ARABIAN GULF CORAL REEFS

Bernhard Riegl, Samuel Purkis  
Nova Southeastern University Oceanographic Center,  
Dania, FL, USA

## Definition

The Persian/Arabian Gulf (herein referred to as the "Gulf") is a subtropical, epicontinental sea situated roughly between 23°50'N and 29°52'N and is therewith home to some of the northernmost coral reefs on the western boundary of the Indo-Pacific (Kharku Island, Iran, at

29°20'N). The Gulf is 989 km long and 50 km wide and has an area of 251,000 km<sup>2</sup>. It has an average depth of 20 m and a maximum of 90 m. Its shallow nature, combined with the high-latitude geographical position and the presence of mountainous plateaus and deserts nearby, make the Gulf's climate the most extreme endured by reef-building corals anywhere in the world. Nonetheless, the Gulf is home to about 40 species of scleractinian and 31 species of alcyonacean corals. The reef fauna represents a small but typical segment of that of the Indo-Pacific.

### The distribution of coral reefs in the Gulf

Coral growth occurs virtually throughout the entire Gulf (Figure 1), with best development on offshore shoals but important fringing systems even along the mainland shoreline (in particular, UAE, Qatar, Saudi Arabia). Relatively few records exist of coral assemblages on the Iranian mainland coast (Shokri et al., 2000; Maghsoudlou et al., 2008), which can be due to runoff from the mountainous hinterland creating unfavorable conditions as well as insufficient records in the literature available in the West. Pleistocene (MIS 7 and 5e) reefs are known from the Iranian islands of Kish (Preusser et al., 2003) and Qeshm (Pirazzoli et al., 2004).

The Holocene transgression is relevant to understanding the present distribution of coral reefs in the region. Flooding initiated approximately 12 kybp (=thousands of years before present) and sea level rose rapidly until

9 kybp from <90 m to <30 m below the present level. This was followed by a more gradual rise until 3–6 kybp when today's sea-level was reached. The gentle basinal slope of the Gulf, combined with a limited depth of only 90 m, made the transgression pass over parts of the shelf extremely quickly, the shoreline position routinely changing by as much as 5 km per century and certainly several orders faster as the homoclinal central shelf was inundated. Here, only an 18-m rise in elevation across a distance of about 500 km exists (Teller et al., 2000). The 4–6-m depth zone, where the majority of corals reside, has only been flooded for <4 ky and, given the lag-time required post-flooding for settlement to initiate, the modern locus of coral growth in the Gulf is relatively young.

### The coral fauna

The total Gulf scleractinian coral fauna is about 40 species (Coles, 2003) and the alcyonacean fauna is 31 species (Samimi Namin and van Ofwegen, 2009), but local diversity is usually lower. The richest local coral fauna is recorded from Saudi Arabia, around Jana and Karan islands (50 species in Basson et al. (1977), which is maybe an overestimation Vogt (1996)). The UAE coral fauna, with 34 scleractinian species, is presently the second richest known from the Gulf (Riegl, 1999). Iran should have a rich coral fauna, probably the richest in the Gulf, due to more benign oceanographic conditions. Local species richness in the Gulf is subject to temporal fluctuations

**Persian/Arabian Gulf Coral Reefs, Figure 1** Areas with extensive coral growth reported in the literature from the Gulf. Areas with confirmed coral growth are shaded gray.

**Persian/Arabian Gulf Coral Reefs, Figure 2** Reef types of the Gulf. Stringers at Bu Tinah. Biostromes surrounding banks like Bazm al Gharbi and headlands like Ras Ghanada. Fringing reefs on offshore islands (Zirku, UAE).

caused by mass mortality events that preferentially affect certain sets of species (Shinn, 1976; Riegl, 1999). A detailed study in Jebel Ali, Dubai, showed six species of *Acropora* to have disappeared regionally after the sea-surface temperature anomaly of 1996, but they later recruited into the area again (Riegl, 2002; Purkis and Riegl, 2005).

Taxonomic composition of Gulf corals is typically Indo-Pacific. Two endemic *Acropora* species (*Acropora arabensis*, Hodgson and Carpenter, 1995; *Acropora downingi* Wallace, 1999) and one endemic *Porites* (*P. harrisoni* Veron, 2000) are known. The taxonomic situation of some species (p.ex. *A. clathrata* and *A. downingi*) is not fully resolved (Wallace, 1999; Veron, 2000; Claereboudt, 2006). The closest faunistic proximity to other reefs of the Indo-Pacific is naturally to the Gulf

of Oman and then the Red Sea (Sheppard and Sheppard, 1991; Veron, 2000) due to a shared paleoceanographic history of restriction during the last sea-level lowstand and simultaneous flooding during the Holocene transgression (Sheppard and Sheppard, 1991; Uchupi et al., 1996). While the Red Sea has marked endemism (18 species), this is not the case in the Persian Gulf (three species, Hodgson and Carpenter, 1995; Wallace, 1999; Veron, 2000). The coral fauna in the southern Gulf (Peninular Arabian coast) is characterized by rarity of alcyonacean soft corals and absence of reef-building hydrozoa, which are common on other high-latitude reefs in the Red Sea and the Indian Ocean. Interestingly, soft coral cover also declines from the northern to the southern Red Sea (Sheppard et al., 1992), where conditions are similar to those in the Gulf.

## Types of frameworks

Corals occur in three biogeologic settings in the Gulf (Figure 2):

Coral reefs consisting of the in situ, interconnected framework built by the corals are small and relatively rare. The rocks of true coral reefs are solid and extend laterally over several tens to hundreds of meters and they form a clearly three-dimensional framework that rises steeply from the surrounding (usually sandy) seafloor and reaches the water surface. Such framework reefs in the Gulf can be subdivided into

- *Fringing reefs*: such as developed around most offshore islands. These classify best as incipient, or at least very young, fringing reefs in comparison with other reef areas, such as the Great Barrier Reef (Hopley et al., 2007);
- *Stringer reefs*: elongated structures, often forming a maze of several parallel and interconnecting stringers of several hundreds of meters (up to kilometers length, for example at Bu Tinah, Mubarratz);
- *Patch reefs*: small, usually round structures of sizes of meters to tens of meters. They are distinguished from

blocks of other substratum by being made up entirely by coral skeletons.

Coral carpets (or biostromes) consist of laterally thin, but continuous frameworks of coral that do not reach the water surface (Figures 2 and 3). Coral carpets are extensive and do not develop into reefs because of (1) underlying flat topography and (2) disturbance history of the local coral assemblage.

Non-framework-building coral communities are sparse assemblages of a few widely spaced corals that generally do not touch or interlock and therefore do not form a framework (i.e., coral rock). They are widely distributed throughout the Gulf (Figures 2 and 3) in any suitable habitat between about 2 and 20 m depth. Generally, biodiversity is much lower than in either coral carpet or coral reef.

## Structure of coral assemblages

The community structure of corals in the Persian/Arabian Gulf is rather uniform (Shinn 1976; Basson et al., 1977; Downing, 1985; Coles and Fadlallah, 1991; Sheppard and Sheppard, 1991; Fadlallah et al., 1995; Vogt, 1996; Riegl, 1999; Purkis and Riegl, 2005; Gischler and

**Persian/Arabian Gulf Coral Reefs, Figure 3** Near-shore habitats typical to the southern Gulf. Near-shore characterized by unconsolidated sediments supporting macro-algae and seagrass. Further offshore, sediments are not in constant motion from wave action and unconsolidated sand sheets rapidly cement to caprock, providing suitable substratum for coral communities.

Lomando, 2005). Assemblages dominated by *Acropora clathrata* or *A. downingi* have been described throughout the Gulf. These usually cap reefs or form well-defined biostromes (Figure 4). Areas of sparse *Porites lutea* or faviid growth occurs widely in sandy environments on caprock. Monospecific nodular *Porites harrisoni* (previously known as *Porites compressa*) are typical of higher temperature and salinity (43–45 ppt) stressed areas in the southern Gulf. *P. harrisoni* or faviids replace *Acropora* dominance in deeper water. During the 1996, 1998, and 2002 bleaching events, *P. harrisoni* and *P. nodifera* had markedly lower mortality than *Acropora*. Thus, these dense *Porites* assemblages may be vestiges of previous mortality events, where the *Acropora* had died and the *Porites* subsequently taken over (Riegl and Purkis, 2009).

### Environmental factors shaping coral assemblages

Responses of coral assemblages to natural stresses in the Gulf have received much attention (Downing, 1985, 1988; Coles and Fadlallah, 1991; Sheppard et al., 1992; Fadlallah et al., 1995; Riegl 1999, 2002; John and George, 2003; Purkis and Riegl, 2005; Riegl and Purkis, 2009). The differentiation of coral assemblages is most likely driven by similar factors in the entire Gulf, which has resulted in similarities in coral assemblage structure.

Differences in the substratum, like the presence of caprock and whether or not overlain by sand (and the grain size of that sand), are important for assemblage composition (Riegl, 1999; Purkis and Riegl, 2005). The Gulf is situated in a strictly arid climatic zone characterized by low rainfall and high evaporation rates (144 cm). Few perennial rivers other than the Shatt el Arab exist, and therefore continuous siltation or sedimentation from rivers is of little concern. However, most of the approximately 4–24 cm per year of rainfall occurs pulsed during the winter months with concomitant delivery of clastic sediment, particularly on the Iranian side, suppressing reef growth near river deltas or areas prone to regular flash floods with strong sediment movement. Winds shape Gulf coral reefs by stirring up sediments and mixing the water column, leading to homogeneously hot or cold conditions. Among the most notable wind patterns is the Shamal (meaning “north”), which tends to set in with great abruptness and force (Murty and El-Sabh, 1984), leading to negative storm surges that can expose shallow corals to air and decrease water temperatures below the lethal threshold for most reefal fauna. Strong local sea breeze–land breeze systems affect reefs by removing water stratification, bringing lethally heated or cooled water to reefal biota. At night, the breezes reverse, which can have a powerful desiccating effect on intertidal biota and coastal vegetation (Sheppard, 1993).

The most powerful climatic determinants of reef growth in the Gulf are temperature and salinity (Figure 5). Over 20°C temperature fluctuations between summer and winter are reported (Kinsman, 1964).

Consequently, species-specific tolerances to temperature and salinity are deciding for assemblage structure. Low tides repeatedly expose corals growing on the shallowest banks to air. Cold-related coral kills occurred in some regions in the winters of 1983, 1985, 1989, and 1992, and heat-related kills in 1996, 1998, and 2002. Temperatures can range from 37 to 14°C. Winter Shamals are often accompanied by low air temperatures chilling the seawater. In Qatar, in 1964, a Shamal chilled air temperature to 0.5°C, surface water to 4°C, and 80 km offshore at 17 m depth water temperature was 14.1°C (Shinn, 1976). Air temperatures approached the freezing point in 1982 off Kuwait, driving sea-surface temperatures to below 7°C (Downing, 1985). In the southern Gulf, fish kills are common following cold or hot weather (Sheppard et al., 1992).

Marked horizontal and vertical salinity gradients exist (Brewer and Dyrssen, 1985). Inflowing surface waters from the Arabian Sea have salinity ~36.5‰, which increases to ~40‰ along the Gulf’s E–W axis (Figure 5). Gulf waters can be differentiated into northern, less saline and southern, more saline realms. Towards the Shatt el Arab, the only continuous freshwater input, salinities decrease to ~36‰. The Gulf’s bottom waters are hyperpycnal. Highest salinities are found on the shallow Arabian side (>41.2‰), from where the deep water on the Iranian side originates (Brewer and Dyrssen, 1985; Reynolds, 1993). The Gulf of Salwah is the most saline area in the Gulf and, consequently, without reef building, and corals are rare to completely absent in its inner reaches.

### Environmental impacts and changes

Gulf coral reefs are naturally restrained by the harsh climate but are additionally increasingly subject to human impacts. Due to its extreme temperature environment, the Gulf has been presented as an ideal laboratory to evaluate coral reef persistence in global change conditions (Riegl, 2003). In the Gulf, reef corals already persist at temperatures that are forecast to affect many more temperate areas soon. Bleaching in 1996, 1998, and 2002 caused severe coral mortality in most of the southern Gulf and in 2007 in Iran (Samimi Namin, personal communication; Maghsoudlou et al., 2008; Baker et al., 2008). Recovery from such bleaching events is variable, but mortalities from nil to almost total have been reported. Stress responses of the corals are frequently species-specific, with the table corals of the genus *Acropora* affected the most during cold as well as hot events. *Acropora* table corals cover most space and build most of the carbonate structure required for reef building; therefore, such mortality has important reef-building consequences and also cause significant losses of associated biodiversity (Figure 4).

Coral predators like the crown-of-thorn starfish (*Acanthaster planci*) and the predatory snail *Drupella cornus* have not been observed in the Gulf, with exception of one specimen each of *A. planci* observed at lesser Tomb

**Persian/Arabian Gulf Coral Reefs, Figure 4** Ecological and taphonomic dynamics of coral assemblages in the Gulf: (a) Dense *Acropora* thickets with interspersed massives like *Porites* and faviids go through cycles of growth and breakdown caused by repetitive mass-mortality events due to extreme temperature (and/or salinity); (b) Breakdown of skeletons takes about 10 years, and therefore if disturbances recur within that timeframe, no lasting frameworks can be formed. This situation is common in the southern Gulf. From Purkis and Riegl (2005).

and Larak Islands (Price and Rezai, 1996). However, sea urchins occur at such high densities that the damage done to corals while grazing has raised some concern. Several coral diseases occur. Black band disease (BBD) is common on branching corals primarily during summer. White band disease (WBD) is usually rare and not infectious even in physical contact situations. Yellow band disease (YBD; Korrubel and Riegl, 1997) is the most widespread and contagious disease both in summer and winter, with fast within-colony spread (~20 mm per week in summer, 10 mm per week in winter). Neither WBD nor YBD are species-specific.

The Gulf has suffered significant loss and degradation of coral reefs and suitable coral habitats. The Arabian

Sea ecoregion (which includes the Gulf) is classified as “critically endangered” by the International Union for the Conservation of Nature (IUCN) and the World Wildlife Fund (WWF) and therefore should be the focus of priority conservation actions. The environmental plight of the Gulf was highlighted by the massive oil pollution following the first Gulf War; however, coral reefs escaped relatively unscathed (Downing and Roberts, 1993; Abuzinada and Krupp, 1994).

Overfishing is of significant concern (Subba Rao and Al-Yamani, 2000) since a lively fishing industry, locally owned but with expatriate fishermen, has sprung up over the last decades. Few of the fishing methods are sustainable, and declines of some fishstock by

**Persian/Arabian Gulf Coral Reefs, Figure 5** (a) Schematic of surface currents and circulation processes in the Gulf (from Reynolds, 1993; Lardner, 1993). (b) Overview of the major salinity trend in the Gulf (Purser, 1973).

around 80% were recorded. Significant depletion in the stocks of pelagic fishes, largely due to fisheries activities in the nursery grounds of some species, may have knock-on effects on the benthic and demersal ecosystems, such as coral reefs, which are also under ever-increasing pressure.

The gravest manmade danger to the persistence of Gulf coral reefs is their destruction due to coastal construction activities. All Gulf States have a history of large-scale dredging and reclamation of shallow marine ecosystems, like coral reefs, which would be considered prime natural assets in many countries and which are, ironically, protected by the national laws of most Gulf States. Coastal construction has led to widespread devastation particularly in the southern Gulf. Post-construction impacts such as thermal and chemical wastewater release, eutrophication, hypoxia, and hypersalinity in artificial embayments and canals, increased sedimentation, and turbidity remain long-term problems (IUCN/MEPA, 1992). Huge construction projects have in some places more than quadrupled the natural shoreline, and with little natural habitat remaining for corals, their next best option is settlement on now-abundant artificial structure, such as breakwaters, etc. They seem to have reasonable success (Burt et al., 2009) and, indeed, artificial reefs appear to be among many Gulf state's favorite construction projects. Conservation of at least some natural reefs, however, would be infinitely preferable.

## Conclusions

- The Persian/Arabian Gulf is home to dense coral communities but relatively little framework-reef building. Major framework types are biostromes, patch reefs, small fringing reefs, and stringer reefs.

- The coral fauna is depauperate but composed of typically Indo-Pacific species (about 40 scleractinia, 31 alcyonacea).
- Coral reefs in the Persian/Arabian Gulf endure the highest annual temperature variability ( $\sim 20^{\circ}\text{C}$ ) of any reef system; consequently, temperature-related mortality is a major factor influencing coral community assembly and reef building. Coral assemblages exist in a regime of repetitive mass mortality followed by regeneration.
- Other key environmental factors are salinity and substratum availability.
- Coral reef biota are under severe pressure of large-scale coastal construction throughout the Persian/Arabian Gulf, which threatens their continued existence.

## PEYSSONNEL, JEAN-ANDRE (1694–1759)

---

James Bowen  
 Southern Cross University, NSW, Lismore, Australia

For 2,000 years it was believed that coral reefs were formed by stony plants (“lithophytes”), a theory which received convincing evidence in 1725 in the world’s first treatise on the “Natural History of Stony Plants” by Luigi Fernando Marsigli di Bologna (1638–1730). Under the heading *Du Corail*, Marsilius as he was known, presented a very detailed study of corals with botanical descriptions of the species examined within the appended catalogue of *Des Madreporées*.

Since their external form obviously resembles plants, Marsilius described what he believed to be calices, branches, leaves, bark, and roots, which he had studied closely with a microscope. At the time his treatise met with wide acceptance and he was invited to London to receive a Fellowship of the Royal Society and Sir Isaac Newton himself insisted on making the award.

Strenuous objections, however, were made by André Peyssonnel, a physician in Marseilles, who believed that coral reefs were not formed by plants but by “insectes” which he confirmed experimentally. Heating the water and noting that, like shellfish, they expanded and stayed out as the temperature rose; dissecting them to determine their structure and the arrangement of the eight radial petals; letting them die out of water and observing that their putrefaction gave a repulsive odor like burning animal; and finally testing them chemically with various kinds of acids to observe responses, he believed they were exactly the same as those made by other marine animals.

In 1726 Peyssonnel sent a résumé of his discoveries in the Mediterranean and Caribbean to the Paris Academy of Sciences, claiming a totally new discovery. Expansion and contraction were evidence of animal behavior, and his dissections revealed that they had exactly the same biological structure, and differed only in size and shape. He was also the first to record qualitative differences between the stem structure and function of two major groups, the soft corals with eight petals *Antipathes* and *Lithophitons*, and the stony, hard, inflexible, reef building *Madrepores* with six petals. Peyssonnel had correctly determined the animal nature of the coral-forming organism, and that reefs were limestone structures created by “insectes” living in large colonies. By 1744 he had completed his exhaustive research under the title *Traité du Corail* which was read to the Royal Society of London on 7 May 1752 and published in a short abridgment.

## PHOSPHATIC CAY SANDSTONE

---

David Hopley  
 James Cook University, Townsville, Queensland,  
 Australia

### Definition

Phosphatic cay sandstone consists of beach materials cemented or replaced by phosphate minerals mainly in the form of dahllite (carbonate hydroxyapatite). In most instances the phosphate is derived from bird guano leached from the surface soils. It can be sufficiently concentrated for it to have been mined for agricultural fertilizer since the early nineteenth century.

### Formation

The phosphatic cay sandstone has formed entirely within the vadose zone (e.g., Stoddart and Scoffin, 1983; Baker et al., 1998), especially on relatively young islands of Holocene age. Surface soils typically 0.6 m thick (the Jemo Soils of Fosberg, 1954) are highly acidic (pH 6–4.5) and play an important role in the concentration of phosphate in what is termed the bird guano model of formation. Guano derived from bird droppings is leached downwards, but the groundwater is neutralized when it hits the alkaline calcareous cay sands beneath the humus layer and precipitation of the phosphate rock occurs.

The fresh water table beneath cays is lens-shaped, rising above mean sea level in the center of the island. The distribution of cemented deposits also has a similar morphology and may be 2–3 m thick in the center of islands but wedges out towards the beach. For example on Raine Island on the northern Great Barrier Reef (GBR) drilling has shown the phosphate not only thicker beneath the island centre but also richer in phosphate. No phosphate was found within or beneath the reef flat adjacent to or underlying the cay (Hopley et al., 2007, Figure 9.3). Coral sands have a great capacity to assimilate phosphate and the resulting sandstone may contain up to 85% phosphate as cements and bioclast replacements (Baker et al., 1998). Stalactite-like columns may be contained within the profile (see Figure 7 in entry Coral Cay Classification and Evolution), reflecting the pathways of downward-moving water in the vadose zone. Subsequent erosion of cays containing phosphatic sandstone

can produce low cliffs formed from the material, fronted by an active beach or berm.

### Relationship with *Pisonia*

There is some discussion about the relationships of phosphatic cay sandstone and stands of pure *Pisonia grandis* forest (e.g., Rodgers, 1992; Fosberg, 1994). These trees produce the necessary high acid soils and are also popular roosting sites for seabirds, the guano of which, derived from fishbones, is largely a calcium phosphate mixture. Both Rodgers and Fosberg argue that in places where *Pisonia* is not present but cemented outcrops occur, it must have been there previously and has disappeared due to natural or man-induced causes (although Fosberg also supports the idea that other species such as *Neea choriophylla* in Belize can produce similar conditions). What does appear to be necessary is a vegetation cover that produces a very acid leaf litter and soil, which react with the downward leaching guano, with *Pisonia* being the most widespread, in the Indo-Pacific.

### An alternative model of formation

Stoddart and Scoffin (1983) described phosphatic sandstone of various kinds, especially the contrasts between the deposits of relatively young (Holocene) cays and those of high islands such as the uplifted atolls of Makatea and Nauru. Rodgers (1992) acknowledged such differences between high and low islands and identified small variations within single deposits, and applying a variety of terms to deposits with only small differences. Fosberg (1994) had used a simple term “atoll phosphate rock” to cover all these nomenclatures.

However, the bird guano model of phosphate accumulation does not seem applicable to the large deposits of high islands and has been rejected for quantitative and qualitative geochemical reasons (Rougerie et al., 1997). Ponds within enclosed or uplifted lagoons are nutrient rich and accumulate mats or “kopara,” rich in chlorophyll and carotenoid pigments. Whole areas of brackish lagoons may be covered by such mats and accumulate to thicknesses of 1–6 m. Partial desiccation results in thick layers of fluorapatite with the potential to produce millions of tons of ore with 30% phosphorous content, clearly an accumulation with which the bird guano model cannot compete.

### Mineralogy

Analyses of phosphate rock from around the world are very similar with dahllite (carbonate hydroxyapatite) being the main mineral in micro laminated grain coatings and bioclast replacement (e.g., Stoddart and Scoffin, 1983; Baker et al., 1998). However, tricalcium phosphate may also appear in the cements, which have a concentration of only 5–8% while the bioclastic replacement values can be as high as 85%. Stoddart and Scoffin (1983) also suggest that pre-Holocene phosphatic sandstones may contain francolite (carbonate fluorapatite) as the fluorine content of insular phosphate gradually increases with time.

### Age and rate of accumulation

The age of phosphate rocks on some high islands may be pre-Quaternary. For example, a Pliocene age has been established for the phosphorite on Navassa Island, just west of Haiti (Miller et al., 2008). However, bird guano deposits occur mainly on young islands of Holocene age. For example, on Raine Island (GBR) the reef flat underlying the deposits has been dated at 4,780 years B.P. while clam shells from within the deposit suggest that phosphatization has occurred in the past 1,200 years only (Baker et al., 1998). Similar ages come from phosphate deposits on Lady Elliott Island at the southern end of the GBR, where reef flat construction dates from 6,500 years B.P. and phosphatization since 3,200 years B.P. (Chivas et al., 1986). Rodgers (1992) notes that phosphatization has occurred in Sakula either as a continuous or episodic process within the vadose zone for at least 4,000 years, that is, for as long as the island has existed.

Few data are available for rates of accumulation, although Chen and Krol (1997) examining nutrient dynamics at Heron Island on the southern GBR produced some relevant estimates. Guano deposition varies seasonally with 164,000 shearwaters (*Puffinus pacificus*) and white cap noddies (*Anous minutus*) depositing nearly 5,000 kg of guano a week over the 19 ha cay during 1992. The guano contains 7.3% N and 1.5% P by weight and thus delivers to the cay surface about 9,800 kg N and 2,000 P annually. The potential for accumulation of phosphatic cay sandstone over the 6,000 or so years of island existence is significant. However, no phosphatic sandstone has formed on this island (see below).

### Phosphatic deposits and eutrophication

The Heron Island study by Chen and Krol (1997) mentioned above aimed at determining the nutrient loading of the islands groundwater both naturally by leached guano and by anthropogenic contaminants. Tidal phenomena dominate the groundwater hydrodynamics and because the groundwater is nutrient rich it has the potential to influence ambient N and P levels in its adjacent reef environment. However, the phosphorous derived from the guano remains on the surface as a thin layer. In the coral cay environment, dissolved inorganic P is absorbed by aragonite and calcite. The coral sediments of the unsaturated zone act as a filter between the P-PO<sub>4</sub> of the groundwater and the adjacent reef flat waters. Chen and Krol (1997) also noted that tidal flushing and the capacity of the reef to assimilate additional nutrients are also factors in limiting the potential for “natural eutrophication” though further research is needed.

### Utilization of phosphatic cay sandstone and resulting environmental impacts

Although phosphatic cay sandstone has varying degrees of cementation, it has a natural significance very similar to beach rock. It can help “armor” the beach face, retard

**Phosphatic Cay Sandstone, Figure 1** The light tower on Raine Island, northern GBR, Australia, built of phosphate rock by convict labor in 1844. In the foreground is the low phosphate cliff (ca 0.5 m) formed by erosion at this end of the island.

erosion by forming low cliffs, and provide anchor points for reorientation of cay beaches.

It has also had wide anthropogenic uses (e.g., Stoddart et al., 1981). Where sufficiently hardened, it has been used as a building stone, one of the most historic sites being the earliest navigational beacon on the GBR built on Raine Island in 1844 by convict labor. It still stands though has required repairs on a number of occasions, (Figure 1).

More widespread is the use of phosphatic cay sandstone as an agricultural fertilizer. This was particularly so in the nineteenth century when thousands of tons were removed from reef islands around the world. This was a particularly profitable industry where phosphate concentrations approached their maximum of about 80%. At most locations the thickest (>2 m) and richest (>50%) occurred in the centre of the islands. Vegetation was cleared, temporary buildings constructed, and even tramways and wharfs built on the most remote of islands.

Environmental impacts were devastating and in some locations recovery has still not taken place (Hopley, 1988, 1989; Daley and Griggs, 2006). *Pisonia* forest has rarely returned but weeds, introduced during the period of exploitation, may now be a permanent feature of the flora. In fact, guano mining is probably the most lasting of all the anthropogenic impacts on GBR islands, having taken place on nine reef islands and one high island (Holbourne), which has an area of Holocene carbonate sediments, similar to the older cays including three

**Phosphatic Cay Sandstone, Figure 2** The central guano flat on Raine Island still largely bare of vegetation 100 years after the end of phosphate mining. The central flat originally had a guano deposit about 1.5 m thick, overlain by a black soil.

phosphatized beach ridge terraces (Hopley, 1975), which were mined between 1918 and 1921 (Daley and Griggs, 2006). The degraded quarry remains as a reminder of the impact of mining on the physical environment. However, on Raine Island and elsewhere on the GBR, the small decline in seabird roosting and nesting appears to be more recent than the time of phosphate mining (1890–1892). Batianoff and Cornelius (2005) relate this to climatic and oceanographic changes in surrounding waters rather than devastation caused by the mining (Figure 2). Sixteen species of birds (some uncommon or rare) still nest on Raine Island, which is also the most important nesting site of the green turtle *Chelonia mydas* in the world (Limpus et al., 2003).

## Definition

*Absolute plate motions* (APM): Motion of tectonic plates relative to a fixed point in the mantle, typically defined by one or more hot spots (i.e., the hotspot reference frame).

*Apparent polar wander* (APW): Motion of the north pole as seen from a moving tectonic plate.

*Relative plate motions* (RPM): Motion of tectonic plates relative to each other, typically inferred from marine magnetic anomalies and the geomagnetic timescale.

*True polar wander* (TPW): Rotation of the entire solid Earth leading to a realignment of the rotation (and geomagnetic) axis.

## Introduction

Reefs build on shallow-water geologic foundations (e.g., continental shelves, tectonically active oceanic islands) that slowly undergo horizontal (due to plate tectonics) and vertical (thermal and flexural subsidence) movements over time. As plates move laterally, coral-rich areas may move to latitudes where coral growth is inhibited (e.g., Grigg and Epp, 1989). Furthermore, long-term plate tectonic changes in the configuration of landmasses can alter the global oceanic circulation, thus affecting the colonization of coral (e.g., Grigg, 1997). Understanding absolute plate motions is thus important for understanding long-term coral variability and the history of global biodiversity patterns (e.g., Renema et al., 2008). The main purpose of this article is therefore to

give an overview of absolute plate motions, the assumptions used, and the current status of plate tectonic research.

Plate tectonics, the major paradigm for how the Earth works, was established in the 1960s following decades of observational research that culminated in the key discoveries of geomagnetic reversals, mid-ocean ridges, transform faults, and seafloor spreading. Collectively, these insights gave rise to the “new global tectonics” or theory of plate tectonics (e.g., Wessel and Müller, 2007). The history of RPM is inferred from the mapping of marine magnetic anomalies and seafloor morphology using implementations of Euler’s theorem for rotations on a sphere. Using improved observations of seafloor morphology derived from multibeam bathymetry and satellite gravity, combined with better coverage of magnetic anomalies, has allowed researchers to improve the resolution of RPM models. The global crustal age models derived from a worldwide compilation of RPM studies (Müller et al., 2008) perhaps best represent the state of the art (Figure 1). However, RPMs do not let scientists examine changes in latitude, and thus an absolute reference frame is needed. APMs typically refer to motion relative to a fixed mantle, and the most prominent mantle reference that has been proposed is the “fixed hotspot” reference frame.

The hotspot reference frame is derived from the geometries of dated hotspot islands and seamount chains

(e.g., Duncan and Clague, 1985) and was introduced by the plate tectonics pioneers Wilson (1963) and Morgan (1971). The foundation of this absolute reference frame, that is, the fixed hot spots, has been the focus of much research during the last few years (e.g., Koppers et al., 2001; Steinberger and Torsvik, 2008; Wessel and Kroenke, 2008). The Hawaii-Emperor chain and its famous bend have been interpreted as the prime surface manifestations of the changing Pacific plate motions over a stationary mantle plume; in fact, this interpretation has reached textbook status. However, over the last decade, a more complicated picture has emerged. Paleolatitudes of the Emperor seamount chain have been inferred from the frozen-in paleomagnetic field, and these imply a birthplace significantly farther north than the present location of the Hawaiian hot spot. The most logical conclusion is that the Hawaiian plume must have been further north in the past and subsequently drifted south (Tarduno et al., 2003). The extent to which such drift contributed to the prominent Hawaii-Emperor bend, now believed to have formed ~47–50 Ma (Chron 21–22), is the topic of ongoing research and has the potential to significantly revise established models of APMs.

### Plate tectonics

Seafloor spreading, a key component of plate tectonics, was developed in the early 1960s (Dietz, 1961; Hess, 1962) when it was first realized that new seafloor is created at mid-ocean ridges, spreads away from them as it ages, and is recycled at subduction zones. However, earlier and remarkably similar ideas had been suggested by Holmes (1944). A key insight came from Wilson (1965), who introduced the concepts of plates and transform faults. Wilson argued that the Earth’s active mobile belts were continuous, marked by active seismicity, and divided the Earth into a set of approximately a dozen rigid plates. These active mobile belts consist of ridges where plates are created, trenches where plates are destroyed, and transform faults that link the other two belts.

Plate tectonics theory states that the Earth’s surface is an interlocking, internally rigid set of plates in constant relative motion. Plates are rigid except at their boundaries, which are weak lines between contiguous plates. Earthquakes occur due to the relative motion between plates; in fact, the earthquakes define the plate boundaries (Figure 2). Three types of plate boundaries are recognized: (1) divergent boundaries – where new crust is produced, (2) convergent boundaries – where crust is recycled as one plate subducts beneath another, and (3) transform boundaries – where crust is preserved as two plates slide horizontally past each other. Complications can arise in some areas. For instance, in places where the boundaries are not well defined, the deformation tends to extend over a broad plate-boundary zone (Gordon, 2000). Such plate-boundary zones tend to have complex geology and deformation, possibly involving one or more microplates.

**Plate Tectonics, Figure 1** Relative motion between plates as evidenced by marine magnetic anomalies. Combined with a geomagnetic reversal timescale, one can create crustal age grids (Müller et al., 2008). The relative motions between plates are very well determined, but it is the absolute motions of plates relative to a fixed point in the mantle that let us examine any changes in latitude that may affect reef colonization.

**Plate Tectonics, Figure 2** Map showing idealized narrow plate boundaries (white lines, Coffin et al., 1997), shallow (0–70 km depth) seismicity (red dots, Engdahl et al., 1998), and regions of diffuse plate boundaries (areas of lighter illumination, Gordon, 2000). ### The morphology of the ocean floor

Wilson (1963) realized that some regions, such as Hawaii, have been sites of long-term volcanic activity. Such focused volcanism would seem to imply that relatively small, stable, and anomalously hot regions (hot spots) exist beneath the plates, supplying high heat energy (i.e., a thermal plume) to maintain the surface volcanism. Wilson suggested that the alignment of the Hawaiian Islands-Emperor seamounts chain must have resulted from the Pacific plate passing over a fixed hot spot deep in the mantle, now located beneath the Island of Hawaii. Morgan (1971) further elaborated on this idea and developed the fixed hotspot hypothesis. About 100 hot spots have been proposed to be active during the past 10 million years (e.g., Burke and Wilson, 1976). The majority are located beneath plate interiors (e.g., the African plate), but others can be found near a mid-oceanic ridge system, such as the hot spot beneath Iceland, the Azores, and the Galapagos Islands. The standard way of reconstructing plates relative to a fixed mantle relies on linear chains of volcanoes that exhibit a monotonic age progression and can be traced back to singular spots of melting in the upper mantle (see *Oceanic Hotspots*). Mapping seamounts thus became an important prerequisite to deciphering APMs.

Even prior to Wilson's realization, it was well known that the seafloor was littered with underwater volcanoes

known as seamounts. During the war, Hess (1946) found and mapped several flat-topped seamounts that he named guyots; these seemed to be former islands that had been worn down to sea level and eventually had drowned. After World War II, a flurry of ocean-going expeditions equipped with echo-sounding instruments heralded major advances in the mapping of seafloor morphology, including the discovery that the oceans possessed mountain chains of extraordinary lengths. These facts were popularized by the famous physiographic maps of Lamont's Heezen and Tharp (1961, 1964), rendering ubiquitous abyssal hills and majestic seamounts. Surveys of seamounts in the Pacific suggested that there might be as many as 100,000 seamounts exceeding a height of 1 km in the Pacific alone (Menard, 1964). Nevertheless, given the vastness of the oceans and the sparse sampling provided by surface ships, the large majority of seamounts were never charted. Statistical analyses of seamount populations were limited to extrapolations from smaller, well-surveyed areas by dense, single-beam echo-sounding tracks or by the improved coverage of the newer multi-beam systems in the early 1980s (e.g., Smith and Jordan, 1988).

Space-age technology brought satellite altimetry as a new technique for the study of oceanography and, indirectly, seamounts. The global gravity maps developed from Seasat altimeter data portrayed a previously unseen

level of detail of seafloor fabric, including numerous underwater volcanoes (Haxby, 1987; Haxby et al., 1983). Using along-track profiles of sea surface heights from the Seasat mission, Craig and Sandwell (1988) pioneered a global investigation into the distribution of seamounts, discovering ~8,500 individual edifices throughout the world's oceans. Key findings were that the Pacific Ocean basin contains most of the seamounts and that in particular the Western Pacific displays an unusual high density of large seamounts. Unfortunately, the large track spacing (~100 km) meant that many seamounts were only partially surveyed and still more were left undiscovered in the gaps between tracks. The later Geosat/ERS-1 altimetry missions greatly improved the coverage by having closer track spacing (a few kilometers) and resulted in much improved global gravity grids (Sandwell and Smith, 1997). Using such grids, Wessel and Lyons (1997) characterized ~8,900 seamounts in the Pacific Ocean alone, with the majority of them being smaller, hitherto uncharted seamounts. Wessel (2001) expanded the analysis globally, finding almost 14,700 seamounts, now adjusted down to 11,800 due to duplicates (Wessel et al., 2010). The size-frequency distribution suggests that sizes of seamounts appears to follow a power-law relationship, which can be extrapolated to match Menard's original prediction of ~100,000 seamounts of at least 1 km in height (Figure 3). Scientists

now routinely study even smaller seamounts (e.g., 50–100 m tall), and should the inferred frequency-size relationship hold for such small seamounts one would predict a global population into the millions. If valid, this would make these morphological features second in ubiquity only to the abyssal hills (e.g., Macdonald et al., 1996).

### The ages of seamounts and oceanic islands

The geometries of seamount chains place strong constraint on plate motions. However, the hotspot hypothesis predicts there should be a monotonic age progression along seamount and island chains formed by hotspot volcanism. Hence, determining the ages from rock samples collected at these sites became another key undertaking. Dredging of seamount flanks and sampling from oceanic islands built up a valuable data set whose importance cannot be overstated (Duncan, 1981; Duncan et al., 1985; McDougall, 1971; Turner and Jarrard, 1982; Turner et al., 1980). Recently, Clouard and Bonneville (2005) reviewed a compilation of more than 1,500 individual age-determinations from ~300 different Pacific volcanoes. The available data seem to suggest that monotonic age progressions are indeed observed along several of the Pacific island and seamount chains, but for others the pattern is less clear (e.g., Dickinson, 1998; McNutt et al., 1997). The key difficulty in assessing age-progressive

**Plate Tectonics, Figure 3** Distribution of seamounts inferred by satellite altimetry (Wessel, 2001). Colors reflect estimated seamount sizes (blue are ~1–2 km, green are 1.5–4 km, and red are >3.5 km tall). Most seamounts are found in the Pacific basin, with significant populations in both the Atlantic and Indian oceans. Hot spots (yellow stars) are often found near the young end of chains. Large igneous provinces (LIPs; orange) are often associated with seamount provinces. Black arrows indicate current absolute plate motions (for scale, the Pacific plate arrow length represents a velocity of 10.8 cm/year).

volcanism is the lack of available samples. Furthermore, as the field of radiochronology has advanced, there is a great need to reanalyze older samples. Finally, the discovery that volcanism at a given site can remain active over an extended period (e.g., Pringle et al., 1991) makes it problematic to determine if the observed age represents the feature as a whole. For instance, in some areas where new samples have been obtained and the latest dating techniques have been applied, significant discrepancies between the new and old dates were found (e.g., Koppers et al., 2004). While such reanalysis is necessary, one must be careful when combining old and new ages in age-progression studies. Surprisingly, some Pacific chains that have geometries similar to the Hawaii-Emperor bend have recently been dated, yielding ages that are incompatible with a hotspot origin (Koppers and Staudigel, 2005). Perhaps the volcanism was instead triggered by transient stresses during times of plate motion changes, leading to decompressional melting that rises up through preexisting zones of weakness (e.g., Sager and Keating, 1984; Wessel and Kroenke, 2007). Such complications continue to make studies of age-progressive volcanism challenging.

Outside the Pacific, the situation is similar: Apparent age progressions are often found for long seamounts chains, but unfortunately both the quality and quantity of samples are much lower than for the Pacific (e.g., Baksi, 1999). It is clear that recent advances in dating techniques promise to raise the quality of radiometrically determined ages to a higher level (e.g., Koppers et al., 2004). However, this will take time, as reanalysis is a time-consuming and costly endeavor. Furthermore, the acquisition of new samples, in particular for older chains, is also a difficult and expensive undertaking and may ultimately require ocean drilling for reliable results (Tarduno et al., 2003). Therefore, the study of APMs is a topic constantly in need of more and better data.

### Studies of absolute plate motions

In recent decades, our understanding of the Mesozoic and Cenozoic RPM between the major tectonic plates has improved considerably, even though APM relative to a “fixed” underlying mantle is still controversial. Marine magnetic anomalies, some as old as 165 million years, along with fossil seafloor fabric based on bathymetry and altimetry clearly constrain RPMs for most of the major plates (Müller et al., 2008). Paleomagnetic data and hotspot traces are among the concepts that have been used to attempt to constrain APM. Paleomagnetic data may provide the paleo-meridian orientation and paleolatitude of a plate; together these determine the paleopole for a given plate. However, because the Earth’s dipole field is axisymmetric, no paleo-longitudinal information is obtained from paleomagnetic data. Hotspot tracks with linear age progressions can be used to restore plates to their original positions by assuming that hot spots are approximately fixed relative to each other (i.e., the “fixed hotspot hypothesis”). However, an early indication

of problems to come appeared when Molnar and Stock (1987) showed that during the Tertiary, the Hawaiian hot spot apparently had moved at 10–20 mm/year relative to the Iceland hot spot and to hot spots beneath the African and Indian plates. Recently, new analyses have questioned the magnitude and significance of this conclusion (Andrews et al., 2006).

Numerous paleomagnetic data sets and models for the APM of the North American, African, and Eurasian plates during the Mesozoic and Cenozoic have been published (e.g., Engebretson et al., 1985). Unfortunately, there are inconsistencies between different apparent polar wander paths and hotspot models. Especially for times prior to 47 Ma, large misfits are found between APM models based on hotspot tracks and those based on apparent polar wander paths from paleomagnetic data (e.g., Sager, 2007). The key plates whose APM forms the basis for our global understanding are the African and Pacific plates.

### Motion of the African plate

Assuming fixed hot spots, Müller et al. (1993) proposed a key African APM model based on a refined model for global RPMs, bathymetry, and radiometric age dates of major hotspot tracks. They combined the major hotspot tracks with observed age progressions from the Atlantic and Indian oceans and employed an interactive technique to derive a “best-fit” qualitative model for motions of the major plates in the Atlantic-Indian domain relative to those hotspot tracks that had clear age progression.

Despite the popularity of this model, it had some well-recognized limitations. The Late Tertiary portion of this model was largely unconstrained by radiometric ages, based on the lack of published age dates. Before 80 Ma, the only hotspot tracks with age progression in the Atlantic-Indian oceans are the New England seamount chain (tied to the Great Meteor hot spot on the Africa plate) and the Walvis Ridge/Rio Grande Rise (likewise linked to the Tristan da Cunha hot spot) in the Atlantic Ocean (Duncan, 1984; O’Connor and Duncan, 1990). Consequently, the APM of the Indian, Australian, and Antarctic plates must be computed by plate circuit closure for these times. When the Müller et al. (1993) model was constructed, pre-80 Ma RPMs in the Indian Ocean were poorly known, due to a lack of data in crucial areas, especially offshore Antarctica in the Enderby Basin and areas south of the Kerguelen Plateau. There, a sequence of Mesozoic magnetic anomalies was subsequently mapped and modeled, originating at ~130 Ma (Gaina et al., 2007; Gaina et al., 2003). However, the Müller et al. (1993) model (incorrectly) assumed a post-120 Ma breakup between India and Madagascar. Disagreements between hot spot and published paleomagnetic reference frames have surfaced for India (Müller et al., 1994) and Australia (Idnurm, 1985), suggesting that the mantle beneath the Indian Ocean cannot be considered a fixed reference frame. This mismatch directly affects estimates of latitude. For instance, paleopoles for India from the

Rajmahal Traps (Das et al., 1996; Rao and Rao, 1996) result in a 47°S paleolatitude of the traps at their time of formation (~117 Ma) (Baksi, 1995), whereas the Müller et al. (1993) model places them at about 40°S; both estimates have an uncertainty of  $\pm 400$  km.

Comparing mid-Cretaceous (122–80 Ma) paleolatitudes of North America and Africa with estimates from hotspot tracks (Van Fossen and Kent, 1992) indicates an 11–13° misfit. This discrepancy suggests that Atlantic hot spots were not fixed relative to the Earth's spin axis before 80 Ma, but moved southwards by as much as 18° (Torsvik et al., 2002) during 130–100 Ma. Others have argued that this apparent southward movement was caused by true polar wander (TPW) (Prevot et al., 2002), but this has been refuted by Tarduno and Smirnov (2002).

The Müller et al. (1993) APM model predicts a relatively sharp bend of plate motion directions (e.g., of Australia and Antarctica) at about 80 Ma. This property originates from the bend between the New England seamount chain and the Corner seamounts at roughly 80 Ma in the central North Atlantic. An equivalent bend in fracture zones is not found in either the Atlantic or Indian Oceans. Revisiting the Africa APM, O'Neill et al. (2005) allowed for moving hot spots in order to satisfy both paleomagnetic constraints and hotspot chain geometry and age progression. They found evidence for plume motion on the order of 5–10° prior to 80 Ma; however since that period any plume motion is less than the model uncertainties. These improvements place India farther north in the past than what conventional fixed hotspot models do.

### Motion of the Pacific plate

The Hawaiian chain is clearly the most studied hotspot chain and has as its most characteristic feature the prominent bend near longitude 172°E, here called the Hawaii-Emperor Bend (HEB; see *Oceanic Hotspots*). Since Wilson (1963) first suggested it, the HEB has been explained by a ~60° change in direction of Pacific plate motion over a stationary hot spot in the mantle (Morgan, 1971). In fact, the geometries of the Hawaii-Emperor chain and many coeval chains (Figure 4) have been used to model the Pacific APM (e.g., Duncan and Clague, 1985; Koppers et al., 2001; Wessel et al., 2006; Wessel and Kroenke, 2008; Yan and Kroenke, 1993). A puzzle, however, was represented by the age of the bend, initially dated to 43 Ma (Dalrymple et al., 1987). Scientists expected that such a large reorientation of the motion of the dominant Pacific plate should have left abundant evidence of contemporaneous tectonic and magmatic events along the plate boundary; however, careful assessments of the geologic record failed to uncover such evidence (Atwater, 1989; Norton, 1995). Furthermore, rock samples obtained from drilling the Emperor seamounts revealed a frozen-in paleomagnetic field best explained if the seamounts had formed significantly further north (5–10°) of the present-day location of Hawaii (Kono,

1980; Tarduno and Cottrell, 1997). Subsequent efforts to project the APM of Africa, via the global plate circuit, into the Pacific failed to reproduce the shape of the HEB (Cande et al., 1995; Raymond et al., 2000). These inconsistencies lead to alternative models where the plume sustaining the volcanism was no longer stationary (Steinberger, 2000; Steinberger and O'Connell, 1998). Such models could fit both the changing latitude of the hot spot (as suggested by paleomagnetism) and the geometry and age progression of the seamount chain. Some researchers concluded that no change in Pacific APM had taken place at all: Since the trail records the vector sum of plate and plume motion, it could be reconstructed by a rapid slowdown in the southward motion of the plume while Pacific plate motion remained unchanged in direction and magnitude (Tarduno et al., 2003).

To reconcile APM models inferred from the Indian, Atlantic, and the Pacific oceans requires their propagation via the global plate circuit (Acton and Gordon, 1994). Because the history of all RPM changes between conjugate plate pairs is not known, the projection of the African APM into the Pacific is subject to uncertainties that cannot easily be quantified. For instance, by choosing a different plate circuit for connecting the Pacific to Australia via the Lord Howe Rise, Steinberger et al. (2004) showed that the HEB did seem to require a plate motion component and thus could not only be caused by plume drift alone. Meanwhile, a reanalysis of the rock samples taken from around the HEB region revealed that the HEB is apparently much older than originally determined. Sharp and Clague (2006) found that the rocks around the bend erupted during the 47–49 Ma interval (Chron 21–22) and, by allowing for 1–2 million year construction time, that the bend itself could have formed even as early as 50 Ma – fully 7 million year earlier than previous estimates. This older age complicates many of the previous conclusions about the lack of correlation between the HEB and plate boundary processes, since Chron 21–22 is generally recognized as an active tectonic period in the Pacific and elsewhere (Cande et al., 1995; Rona and Richardson, 1978). Sharp and Clague (2006) examined details of the age progression and concluded it was unlikely that the plume was moving during the formation of the bend, thus favoring the original explanation (purely a plate motion change over a stationary hot spot) for the origin of the HEB.

### Discussion

APM studies continue to be carried out in the aftermath of these discoveries. For instance, Whittaker et al. (2007) presented new tectonic evidence for a change in plate motion between Australia and Antarctica; this kink appears to coincide in time with the HEB. This change in plate motions may further affect the global plate circuit and results that are derived from its use.

Recently, the case for moving hot spots was reviewed by Tarduno et al. (2009). They argued that mantle-scale flow models could explain the types of plume drift

**Plate Tectonics, Figure 4** Map of the Pacific hemisphere with location of dated rock samples (*triangles*) from the Hawaii-Emperor (HI; *red*), Louisville (LV; *blue*), Foundation (FD; *green*), Pitcairn (PC; *magenta*), Caroline (CR; *yellow*), Cobb (CB; *black*), and other Pacific seamount chains (*white*). *Red (blue) stars* represent presently active (extinct) hotspot locations, while solid lines represent the WK08-G APM model geometry (Wessel and Kroenke, 2008); ellipses indicate 95% confidence regions. *White stars* represent active hotspot locations for chains not used to constrain the APM model. *Heavy dashed lines* represent the 15 inter-hotspot separations between the six chains identified. *Dark red lines* are plate boundaries (redrawn from Wessel and Kroenke, 2009).

inferred from the Hawaiian plume by the observed paleolatitudes from the Emperor seamount chain. In fact, they suggested that hotspot tracks, rather than constraining the APM, may instead give insight into the patterns of past mantle convection. At the same time, the distances between same-age samples in the Hawaii-Emperor and Louisville chains were analyzed, suggesting relatively minor changes in the separation of these two hotspots through time (Wessel and Kroenke, 2009). In the critical time period 80–47 Ma, this separation decreased by perhaps 3–5° (Figure 5), compared to 7–9° predicted by moving hotspot models (Koppers et al., 2004; Steinberger and Gaina, 2007). There appears to be several ways

to satisfy both the quantified distance constraints and the observed paleolatitudes: (a) if the Hawaii plume was farther north at 90 Ma but moving southward (to satisfy the paleolatitudes), then the Louisville plume must have been much farther north as well (to match the observed hotspot separations). Given the variability in modeling results of the Louisville plume motion (e.g., Antretter et al., 2004), it is possible that a combination of boundary conditions and mantle viscosities will be found that will predict plume motions for Hawaii and Louisville that satisfy both distance and paleolatitude constraints; (b) perhaps plume drift only accounts for a part (e.g., 5°) of the observed paleolatitudes and the remainder should be attributed to

**Plate Tectonics, Figure 5** Examination of distance deviations,  $\Delta(t)$ : the distance between coeval points on different chains minus their present (*fixed*) hotspot separation. The *polygons* represent continuous estimates of  $\Delta(t)$  with assigned uncertainties. *Triangles* show  $\Delta(t)$  for locations of dated rock samples and their estimated coeval locations on other chains. *Dashed line* indicates typical prediction of  $\Delta(t)$  for Hawaii and Louisville from mantle dynamic modeling (Steinberger and Gaina, 2007), with *dotted line* the (t) for the model of Koppers et al. (2004). Scatter due to age uncertainties (not analytic errors, but uncertainties associated with the timescale of volcano building) seems contained within a  $\pm 2^\circ$  window (Redrawn from Wessel and Kroenke, 2009).

TPW (e.g., Duncan and Richards, 1991); or finally (c) the interaction between the Hawaii hot spot and the Kula-Pacific ridge may have lead to the entrapment of plume melt by the ridge (Wessel and Kroenke, 2009). This interaction may have forced surface volcanism due to the plume to erupt closer to the ridge axis (instead of vertically above the plume), particularly after the ridge overrode the plume at  $\sim 78$  Ma. The overall effect would be to distort the oldest age-progression data but also result in more northerly paleolatitudes. While option (c) is not new (Sleep, 1996; Small, 1995; Tarduno et al., 2003) and could perhaps account for  $\sim 4^\circ$  of deviations (which is close to the  $\sim 5^\circ$  we observe), it remains a scenario that is difficult to test. Note, however, that if seamounts formed closer to the ridge than the hotspot location would imply, then the observed age progression would at first be slower but then accelerate as seamounts again begin to form vertically above the hot spot; of course, this scenario reflects the observed Emperor age progression (Sharp and Clague, 2006) and sense of paleomagnetic latitude shifts (Tarduno et al., 2003). Option (b) is a compromise model that allows for most of the HEB change to originate from a plate rather than plume motion change, as supported by contemporaneous global tectonic events (Rona and Richardson, 1978; Wessel and Kroenke, 2008). The implied small amount of TPW ( $< 5^\circ$ ) should be permissible given the

present uncertainties in global paleomagnetic reconstructions (Steinberger and Torsvik, 2008) and the physics of TPW (e.g., Tsai and Stevenson, 2007). The latitudinal shift from TPW would combine with the (reduced) plume motion to satisfy observed paleolatitudes. Finally, option (a) explains the HEB by manipulating plume motions only (Tarduno, 2007; Tarduno et al., 2009); it predicts that most of the north-south APM proposed for the Pacific plate is an artifact of misinterpreting plume drift for plate motion (Figure 6). This model has the benefit of being testable, provided reliable paleolatitudes someday will be determined for the oldest Louisville seamounts. Tarduno et al. (2003) notes the lack of coral reefs on drowned Emperor seamounts north of Koko and cites this as support of more northerly latitudes during the late Cretaceous. However, the absence of evidence is not a strong evidence of absence, and it thus remains possible that the paucity in Emperor seamount reefs is instead linked to palaeoceanographic events (e.g., Grigg, 1997).

### Summary

Reefs that form on continental shelves and the flanks of hotspot islands will experience latitudinal, oceanographic, and climatic changes as the tectonic plates they are part of move over the mantle through geologic time.

**Plate Tectonics, Figure 6** Alternative Hawaii-Emperor geometries. (a) Observed track with ages and inferred period of rapid hotspot motion. (b) Different plate circuits are obtained by using Lord Howe Rise (*white arrows*) instead of connecting West and East Antarctica (*solid arrows*). (c) Differences in predictions of the HEB by projecting Africa APM via different global plate circuits. Regardless of the circuit used, the HEB is poorly predicted. (d) Predicted geometry of the Hawaii-Emperor seamount chain if the Hawaiian hot spot had remained stationary (modified with permission from Tarduno et al., 2009).

Traditionally, models for Pacific APM have had a large northward component during the late Cretaceous, resulting in considerable latitudinal changes for reefs originally in the tropics. However, recent paleolatitude studies from the Emperor seamounts suggest that this northward plate motion is an overinterpretation (or possible a misinterpretation) of the data, and that we instead are seeing the effect of a mostly westward-drifting plate

moving relative to a rapidly southward-moving mantle plume during the 80–47 Ma timespan. If this scenario can be verified by additional high-quality paleolatitude observations from other Pacific chains, in particular the Louisville chain in the south, it will force a major reassessment of all APM models and consequently any geologic hypothesis that relies on plate tectonic control on the evolution of coral reefs.

## PLATFORMS (CEMENTED)

---

Roger McLean  
 University of New South Wales, ACT, Canberra, Australia

## Synonyms

Benches; Breccia sheets; Conglomerate platforms; Pavements; Promenades; Rampart platforms; Rock ledges

## Definition

Platforms are horizontal or sub-horizontal, planar surfaces of cemented coral rubble, typically 0.5–1 m thick,

overlying reef flats away from the reef front, and often partly covered by island deposits or mobile sediments.

Cemented platforms are common on the exposed windward side of Indo-Pacific reefs that have islands or *motu* (*Atoll Islands (Motu)*). Platforms are often continuous and have a fairly constant height, though there are variations in surface elevation from reef to reef, and some reefs have platforms at more than one level. Many platforms are exposed above the present level of high tide and have a scarped seaward face or a step down to the reef flat. Inspection of both scarps and surfaces reveal that platforms are made up of poorly sorted, skeletal materials such as coralline algae, mollusks and especially clasts of coral rubble, the latter including branching and massive corals of sizes up to several decimeters. Such rubble is consistent with primary or secondary storm deposits, that have been subsequently cemented into coral conglomerate (Montaggioni and Pirazzoli, 1984) or rampart-rock (Scoffin and McLean, 1978). That is, platforms are the lithified equivalents of coral rubble sheets accumulating on reef flats at the present time.

The broad, planar surfaces of cemented platforms, often called promenades or pavements, led some workers to conclude that they owed their flat top to marine erosion, though now the weight of evidence clearly favors a depositional origin. To facilitate lithification such deposits have to be stationary for some time. They also require some fine interstitial sediment to aid in the retention of saturated waters at grain contacts. Examination of samples from platforms on atolls in French Polynesia and the low wooded islands on Australia's Great Barrier Reef, have shown the cementing medium to comprise acicular aragonite, and/or high magnesium calcite and micrite, preferentially distributed throughout an outcrop, and, between platforms at different levels.

Radiometric ages of cemented platforms associated with modern reef tracts in the Indo-Pacific range from the present through 6,000 year BP. There is, however, a clustering of ages between 3,000 and 6,000 year BP for the extensive coral conglomerates in French Polynesia that reach an elevation of more than 1 m above the present mean tide level; for the widespread upper platform on the Great Barrier Reef; and, for the elevated platforms that underlie most islands on Cocos (Keeling) atoll in the eastern Indian Ocean. In all these cases the platforms have been interpreted as indicating a relative sea level higher than present at the time. By contrast, cemented platforms are minor or absent in Western Atlantic reefs because these reefs have only recently caught up with sea level.

## POLEWARD EXTENSION OF REEFS

Colin D. Woodroffe  
University of Wollongong, NSW, Wollongong, Australia

### Definition

Coral reefs are primarily tropical but extend into mid latitudes. Poleward extension considers the factors that limit reef growth at the latitudinal limit and the potential for further extension into subtropical waters.

### Introduction

Global climate change poses particular challenges for coral reefs with the expectation that reefs will become increasingly degraded as a consequence of bleaching associated with a rise in sea surface temperatures and reduced calcification resulting from ocean acidification (Kleypas et al., 1999). However, a further possible, and perhaps more positive, response to global warming might be a poleward shift of the latitudinal limit to reef growth (Buddemeier et al., 2004; Precht and Aronson, 2004).

### The latitudinal limit to reef growth

The suggestion of poleward extension of reefs as a result of global warming is based on the premise that it is temperature which imposes the limit to the present distribution of reefs, particularly at their latitudinal limit. Reef growth is prolific in warm tropical waters, but reefs become more marginal where sea surface temperature is around 18°C. The distribution of reefs along the coast of Japan shows a strong relationship with temperature, and there is good correlation between species abundance and sea surface temperature (Veron and Minchin, 1992).

The latitudinal limit to reef formation, however, appears to be related to a series of factors, of which temperature is only one. Competition with other organisms is also significant. For example, macroalgae such as the kelp *Ecklonia radiata*, are extensive on reefs on the Abrolhos Islands (29°S) off Western Australia (Johannes et al., 1983), whereas coralline algae replace corals, particularly at depth on the Elizabeth and Middleton reefs (29–30°S) and Lord Howe Island (31°30'S) in the Tasman Sea (Kennedy and Woodroffe, 2004; Woodroffe et al., 2006). High sediment loads and turbidity may limit other high-latitude reefs, such as those on Inhaca Island (32°54'S), southern Mozambique (Perry, 2003). The highest latitude reef appears to be at Iki Island off Japan, where a reef as far north as 33°48'N has been described (slightly further north than reefs around Bermuda which

occur at 32°50'N), that has withstood winter sea surface temperatures as low as 13.3°C (Yamano et al., 2001).

The composition of carbonate sediments changes at the latitudinal limit to coral-reef formation, with the coralline assemblage (dominated by coral and coralline algae) of tropical waters being replaced by a foramol assemblage (foraminifera and molluscs). There are also significant physical differences. Volcanic islands that lie outside reef seas are exposed to marine abrasion and are generally flanked by steep cliffs and broad near-horizontal shelves (Menard, 1986), whereas a protecting reef attenuates wave energy, and the volcanic landscapes that develop behind such a reef are generally characterized by more gentle hill slopes.

The latitudinal limit is considered a sensitive threshold to coral reef establishment and has been called the Darwin Point (Grigg, 1982). On the Hawaiian Islands, where this threshold marks the change from reefs, such as Midway Atoll and French Frigate Shoals, to the Emperor Seamount chain, the effect is accentuated because of the rate at which the plate is migrating and the rate at which islands are subsiding. The latitudinal limit to reef formation can therefore be a function of the interaction of several factors of which temperature is only one aspect.

### Daly and marginal seas

Reginald Daly believed that Quaternary climate and sea-level changes had been accompanied by substantial shifts in this latitudinal limit to coral-reef development. Daly inferred that the level of the sea had changed throughout the Quaternary as a consequence of the expansion and melt of the ice sheets, and he realized that these sea-level fluctuations had particular implications for reefs. He postulated that there must have been *marginal seas* from which reefs had been eradicated during ice ages, with gradual re-establishment during the postglacial (Daly, 1915, 1934). Sea-surface temperature reconstructions at the glacial maximum, undertaken as part of CLIMAP (1976) revised this view, and demonstrated that there had not been such marked shifts in the 18°C isotherm as had been expected. This implied a less significant contraction of the poleward limits to reef development than inferred by Daly.

### Holocene changes in range

Contrary to the gradual expansion that might have been anticipated under the marginal seas hypothesis of Daly, coring and radiometric dating of reefs close to their latitudinal limit has often revealed that these reefs have shown vigorous growth during the postglacial. In the Abrolhos, for example, there is more than 20 m of Holocene reef that appears to have accumulated at average vertical growth rates of 6–7 mm/year, generally keeping pace with postglacial sea-level rise. Reefs were established at sea level around 6,000 years ago when sea level stabilized close to its present level in this part of the world (Eisenhauer et al., 1993; Wyrwoll et al., 2006). Holocene reefs similarly accreted vertically, and the modern reef

rim morphology had also established by the time of sea-level stabilization, on Elizabeth and Middleton Reefs in the Tasman Sea (Woodroffe et al., 2004). The Holocene history of reef growth on Lord Howe Island implies that a reef structure was in place at least by 5,000 years ago and rapid lagoonal sediment infill was occurring in its lee (Kennedy, 1999; Kennedy and Woodroffe, 2000).

There is also evidence that reefs have been more prolific at the latitudinal limit during mid Holocene than at present. Veron recorded a reef at Tateyama, near Tokyo in Japan, that is now fossil but which contained 72 species 6,000–5,000 years ago, about twice the present diversity of nearby reefs, on the basis of which temperature appears to have been 1.2–1.7°C warmer than present (Veron, 1992, 1995). An early Holocene reef also flourished along 85 km of the southeastern Florida coast, 9,000–7,000 years ago (Toscano and Macintyre, 2003). Coral is presently found in luxuriant communities at several places in the lagoon on Lord Howe Island (Harriott and Banks, 2002); coring and dating of lagoonal sediments, however, implies a phase of more prolific coral growth in mid Holocene (Woodroffe et al., 2005).

### Pleistocene reefs beyond the present latitudinal limit

There is some evidence to suggest that reefs have flourished further poleward at times in the past; for example, limestones of last interglacial age are prominent in Florida. By contrast with the Holocene, greater poleward extent has been interpreted for reefs during the last interglacial from several sites. In Australia, the well-developed reef at Fairbridge Bluff on Rottne Island (Szabo, 1979) suggests more prolific coral than occurs there at present, and that a reef formed, where today only scattered coral communities are found. Greenstein and Pandolfi (2008) indicate that the coral biodiversity of reefs of the Last interglacial age along the coast of southern Western Australia, particularly at the Abrolhos Islands and Rottne Island was considerably greater, with a more tropical assemblage of taxa than that presently found along this coast. They imply that these species might migrate south under future warmer conditions.

Corals occur in last interglacial deposits at Evans Head, on the coast of New South Wales, further south than they presently reach on this coast (Marshall and Thom, 1976). At Lord Howe Island there is some evidence of former Pleistocene reefs revealed by shallow coring in the lagoon (Kennedy et al., 2007), but there is also an extensive fossil reef system in water depths of around 30 m on the shelf around the island (Woodroffe et al., 2006). These provide evidence of conditions warmer than present during the last interglacial in that they reached further south than in the late Holocene.

### Future global warming and the limit to coral growth

Concern about future climate change has reinvigorated concern about the limits to reef growth (Guinotte et al., 2003;

Buddemeier et al., 2004). Discovery in 1998 of the recent establishment of the branching coral *Acropora cervicornis* off the coast of Fort Lauderdale in Florida (Vargas-Angel et al., 2003), contrary to an almost Caribbean-wide trend of coral deterioration, provides one of the first indications that global warming may result in extension of coral range (Precht and Aronson, 2004).

However, it seems that warming may only result in a small increase in potential reef habitat. It is also necessary to take other factors, such as genotypic diversity and gene flow into account, as these can be significant constraints at the latitudinal limits to reef growth (Ayre and Hughes, 2004).

### Summary

In the face of concern about the impact of global warming, particularly in relation to coral bleaching and the threat of thermal stress on tropical reefs, there has been reawakening of interest in marginal reefs. However, it is doubtful if there is much scope for extension of reefs further poleward. Many mid-ocean settings at which reefs are presently marginal represent the limit of land that would be suitable; for example, there are no islands further north of Bermuda or south of Lord Howe Island to which corals could extend. Similarly there is an absence of suitable habitat on many of the mainland coasts beyond the present limit. Where corals are able to colonize, they will be subject to a plethora of other stresses, pollution, sedimentation, and the effects of ocean acidification which are likely to be felt first in these higher latitude settings.

## Definition

*Porites* (Phylum Coelenterata, Class Anthozoa, Order Scleractinia) is a genus of colonial, zooxanthellate scleractinian coral.

## Introduction

*Porites* are major coral components of reefs, both in the fossil record and in living reefs, in which they can be the most important framework builder. *Porites* can be found in almost all reef habitats. The genus includes large massive species (Figure 1), which are often a dominant component of back reef coral fauna, but also commonly found on the seaward slope and reef flat. Smaller massive specimens also occur in a wide range of reef environments. The genus also includes encrusting and branching species, the latter of which are more common in protected environments, often forming large monospecific stands on the back reef slope and other lagoonal areas. Skeletal banding and isotopic composition of massive *Porites* skeletons provide invaluable records of colony growth rates and past environmental conditions.

## Colony formation and skeletal detail

*Porites* colonies of all shapes are formed by extratentacular budding. Corallites are small (up to 2 mm diameter) with synapticulothecal walls. Corallite septa are arranged in two cycles (Figure 2). They are perforated, being formed by three to four vertical trabeculae loosely connected by horizontal rods. In some septa, the

**Porites, Figure 2** Comparison of the septal plan of *Porites* and the closely related genus *Goniopora*. It is suggested that *Porites* is a derivative of *Goniopora* by reduction and disappearance of the third septal cycle.

innermost trabeculae may develop as pali. Lateral sides of septa are connected by synapticular rings, and there is a columella comprising a single trabecula.

### Palaeontological and taxonomic history

The genus *Porites* was established by Link in 1807, with the Atlantic species *Porites porites* (Pallas, 1766) as type species. Later, Gray (1842) established the family

Poritidae, notwithstanding the fact that the genus *Goniopora*, created by De Blainville in 1830, which includes species dating back from the middle cretaceous, has a longer palaeontological history. The family is a mid-cretaceous derivative of the Actinacididae that, together with the closely related family Microsolenidae, can be traced back in the fossil record to the Triassic-Jurassic boundary. The genus *Porites* is probably derived

from *Goniopora* during the Eocene by a reduction in the number of septa, from 24 (3 cycles) to 12 (2 cycles), and by a decrease in the average number of septal trabeculae, from 4–8 (*Goniopora*) to 3–4 (*Porites*). The one exception to the dodecameral septal arrangement in the genus *Porites* is *Porites decasepta* described by Claereboudt (2006) from the Gulf of Oman.

A closely related monospecific genus, *Stylaraea* Milne Edwards & Haime, 1851 has been considered in the past by some as a junior synonym of *Porites*, but it is now widely accepted that *Stylaraea* is a genus in its own right. The taxonomic position of *Synaraea* Verrill, 1864 and *Napopora* Quelch, 1886 is less clear. The latter, considered as a synonym of *Synaraea* by Wells (1956) itself treated as a subgenus of *Porites* by the same author, is considered as a subgenus of *Porites*, but distinct from *Synaraea* by Veron and Pichon (1982). There could be a case, on the basis of micro-structural considerations, to re-establish *Synaraea* as a genus in its own right. The relationships of two recently described monospecific poritid genera, *Poritipora* Veron, 2002 and *Machadoporites* Nemésio, 2005 (the latter originally named *Calithiscus* by Claereboudt and Al-Amri [2004]), remain uncertain and will require morphometric and molecular genetic analyses to be clarified.

### Geographic distribution

The genus *Porites* is found in both the Atlantic Ocean and the Indo-Pacific Ocean, but there are no species in common between the two areas. There are only four species in the Atlantic Ocean: *P. porites*, which can reach up to 1.2 m maximum colony size, *P. astreoides*, *P. branneri*, and *P. colonensis*, the latter sometimes regarded as a junior synonym of *P. astreoides*. In the Pacific Ocean, more than 140 nominal species have been described, but the number of valid species is unquestionably much lower. A number of species including some with very large, massive colonies that play a major role in the construction of the reef framework are of particular interest due to their large distribution range. They occur from the northern Red Sea south to Madagascar and Mozambique, and in the Pacific Ocean, east to French Polynesia. Many species, however, have a more restricted geographic regional or local distribution (e.g., *P. compressa* restricted to the reefs of the Hawaiian Islands) even though they may be a major and even dominant component of the coral communities within their area of distribution (e.g., *P. harrisoni* in the Arabo-Persian Gulf and *Napopora irregularis* in Polynesia).

### Colony shape and size

*Porites* has attracted the attention of reef biologists by the fact that, for a handful of Indo-Pacific species, individual colonies are massive, and can reach enormous sizes, several meters across and several meters high, up to nearly 10 m (indeterminate growth). These species include *P. lutea*, *P. lobata*, *P. australiensis* and *P. solida*

in particular, and their importance stems from the fact that both in the fossil record and in living reefs (e.g., Done and Potts, 1992), they are often the principal reef framework builders. A larger number of species, however, have generally a much smaller average colony size, sometimes no more than a few centimeters across. Besides the typically massive and often large sized colonies, a variety of colony growth form occurs, including encrusting, lamellar (*P. lichen*), branching (*P. porites*, *P. branneri* in the Atlantic Ocean, *P. cylindrica* and *P. nigrescens* in the Indo-Pacific Ocean). Some species have columnar, nodulose or even more irregular, and at times somewhat ill-defined, growth forms.

### Ecological requirements

#### Temperature

A number of *Porites* species are very tolerant to extremes of seawater temperatures, and hence have a very large geographic distribution. This is the case in particular for the large massive species such as *P. lobata* and *P. lutea*. The latter especially is to be found in seasonally very warm (>32°C), but also very cold (15°C) waters such as in the northern Arabo-Persian Gulf. It also tolerates permanently high (e.g., Gulf of Tomini, Sulawesi, ca. 30°C) or cool waters, down to 21–22°C sea surface temperature (SST) mean annual SST (e.g., Rapa, Austral Islands). In many high latitude reefs, however, the genus is either absent (Kermadec Islands, 29°12' S, mean annual SST 21°C) or represented by only one species: *P. lichen* at Lord Howe Island (31°30' S, mean annual SST 21°C) or *P. lobata* at Easter Island (27°07' S, mean annual SST 22°C). It is to be noted that both high and low extremes of seawater temperatures can trigger a bleaching event (discoloration of the living tissues due to a breakdown of the symbiotic association), which in many instances is followed by a recovery of the colonies affected. Severe bleaching associated with significant SST anomalies, however, may lead to partial or even total mortality of the colonies concerned.

#### Salinity

Like many other coral genera, *Porites* species better tolerate high salinity than low salinity, which limits coral development in the vicinity of estuaries and river mouths. Occasional or accidental decrease in salinity associated with freshwater plumes of flooding coastal streams or rivers may cause partial or total bleaching of *Porites*, which may lead to partial or total mortality of the colonies. A number of species can thrive in areas where salinity is permanently and significantly higher than normal, and up to at least to 42‰, such as the Red Sea and the Arabo-Persian Gulf. Many large massive or columnar species are common throughout the Red Sea (where they were frequently used as building material) and colonies of *P. lutea* and *P. harrisoni* up to several meters across are very common in the coral reefs of Kuwait. The combined effect of temperature and salinity has a synergistic effect on the level of stress and survival of corals, and

*Porites* tolerance to extremes for both factors makes the genus a dominant feature in coral reefs developed in harsh environments.

### Light

In the natural environment, light intensity and quality is associated with other environmental factors such as depth, water transparency, and emersion. Light requirements are, to a large extent, species-specific, but various species of *Porites* can be found at both ends of the light intensity range. Species such as *P. murrayensis*, *P. stephensoni*, *P. lutea*, *P. lobata*, or *P. somaliensis* tolerate exposure to full sunlight at low tide on the reef flats for several hours. Conversely, several large massive species including, *inter alia*, *P. lutea* and *P. lobata* can occur on the deep fore reef slope.

### Sedimentation

In addition to the various mechanisms that have been developed by scleractinian corals to eliminate fine particles which deposit on the colony surface (ciliary currents, tentacular movements), several species in the genus *Porites* produce abundant sheets of mucus, which covers and protects the living tissue, and on which the fine sediment particles get trapped. After some time, generally up to a few weeks, the sheet of mucus is eliminated, thus removing the sedimented particles, and the process may start again. Overall, *Porites* species cope well – within limits – with significant levels of fine particle sedimentation, hence their dominance in areas such as back reef slopes, fringing reefs, or deep embayments.

### Water motion

Despite the fact that many of the species build very large massive colonies, which seemingly would resist strong currents or pounding by breaking swell and waves, large specimens of massive *Porites* are rarely found in areas of very high hydrodynamic energy such as the shallow reef front. This situation may be due to a combination of factors: on the one hand, the area of attachment of massive species on the substratum is much smaller than the large size of the colonies would suggest, and further the colony is often not very firmly adherent to the reef; on the other hand, in such environments, *Porites* is out competed by other (r-strategist) genera such as *Acropora* and *Pocillopora*, or even by crustose coralline algae. As a result, large *Porites* specimens are more commonly found in more protected reef zones such as the reef flat and the reef slopes. Local and regional variability in the abundance and size frequency distributions of massive *Porites* colonies also reflects variability in both the prevailing wave climate and the return period between cyclonic waves strong enough to dislodge corals of different sizes at different depths (Massel and Done, 1993).

### Emersion

A number of *Porites* species found of the reef flat may be fully emerged during low spring tides and exposed to full

sun during daytime, for up to several hours. They include species restricted to that type of environment (*P. murrayensis*, *P. stephensoni*) but also species with a larger cross-reef distribution such as *P. lutea*, *P. lobata*, and *P. australiensis*. The ability of such species to withstand exposure to air, and in particular desiccation, stems from the fact that the three-dimensional structure of the skeleton acts as a wick, pumping water from residual pools of seawater or from water-logged sediment and bringing it to the soft tissue which are as a result kept sufficiently moist. Thus, *Porites* species are often, in terms of vertical distribution, some of the highest corals to be found on the top of the reef buildup.

## Population biology

### Reproduction

The majority of the Indo-Pacific species of *Porites* are gonochoric (separate sexes), spawning gametes, although occasionally a few hermaphroditic polyps or colonies are found, and they reproduce only once a year (Harrison and Wallace, 1990). In contrast, the Atlantic representatives of the genus are hermaphroditic and up to nine reproductive cycles have been recorded for *P. astreoides* (Szmant, 1986). This situation can be explained by the fact that the faunas of the two regions have been separated for more than 10 million years, hence there has been evolutionary divergence resulting in contrasting sexual patterns. Little is known of size/age at first reproduction. Harriott (1983) gives a colony diameter of less than 8 cm for gravid *P. australiensis* and *P. lutea* (which have massive growth forms) For the branching *P. astreoides* in Panama, first reproduction occurs when the average branch length reaches 8.4 cm, the smallest reproductive colony having a dimension of 3 × 2 cm (Soong and Lang, 1992). However, polyp fecundity in female colonies is correlated with branch thickness but not with age (Chornesky and Peters, 1987). For branching species in general, the tips of the branches are infertile (juvenile polyps) as are polyps at the base of the colonies. There are no data specifically for *Porites* species on the duration of the planktonic larval stage and larval dispersal. With respect to larval settlement, laboratory experiments have shown that for *P. porites*, larval settlement is patchy as a result of aggregated settlement behavior (Goreau et al., 1981). Like many other corals, growth rates in the first year after settlement are low and mortality very high. Quantitative data are scarce: Vaughan (1912) gives a figure of 4 × 3 mm after a year for the slowest growing *Porites* spat, with up to 14 × 23 mm for an agglomeration of six planulae.

Among the various modes of asexual reproduction, breakage, survival, and subsequent regrowth of coral fragments are common occurrences for scleractinian corals (Highsmith, 1982). This reproduction strategy occurs in large, massive, *Porites* species (Done and Potts, 1992) but it is probably more frequent in columnar species and branching species such as *P. cylindrica* and *P. nigrescens* on the Great Barrier Reef (Resing and Ayre, 1985) and

*P. compressa* in Hawaii (Hunter and Kehoe, 1986). At population level, Hunter (1985) presented evidence of predominantly clonal populations for *P. compressa* in Hawaii, but at a broader geographic scale the relative importance of asexual reproduction has not been fully assessed for most of the dominant, reef-building species.

### Growth and growth rates

Growth in the genus *Porites*, in particular retrospective growth in massive species, has been the subject of particular attention. This attention reflects their paramount importance as primary reef builders, and hence their role in coral reef development and maintenance. Growth in massive *Porites* is particularly amenable to a study by radiographic techniques (“density banding”), which rely on the seasonality in the density of calcium carbonate deposition. In most cases, yearly skeletal accretion includes a dark band (period of intense  $\text{CaCO}_3$  deposition) and a lighter band (period of lower  $\text{CaCO}_3$  deposition). For a general review of coral growth, refer to Buddemeier and Kinzie (1976). Radiographic analyses of density banding in cores obtained from large massive *Porites* show that:

- Many large colonies are more than 100 years old, and some even reach an age of 700 years or more.
- Average growth rates (radial increment) vary between 8 and 18  $\text{mm year}^{-1}$  for unstressed corals, with extremes of ca. 3  $\text{mm year}^{-1}$  for *P. lutea* at Enewetak (Highsmith, 1979) and 22.7  $\text{mm year}^{-1}$  for *Porites* sp. on the Great Barrier Reef (Lough and Barnes, 2000).

For massive *Porites* with a 0.2–0.5 m colony height range, growth rates along the vertical axis ( $13.0 \pm 3.4 \text{ mm year}^{-1}$ ) are significantly higher than along the horizontal axis ( $10.9 \pm 3.2 \text{ mm year}^{-1}$ ) (Lough and Barnes, 2000). In the particular case of colonies living on the reef flat, and especially in areas of significant tide range, however, the situation may be reversed. After some time, the vertical growth of the massive and often hemispherical colony becomes limited by the emersion of the top of the colony at low tide, while it continues to grow horizontally, taking an irregular disc shape. The upper surface dies and sometimes becomes the settlement site of other corals, or may be the subject of intense bioerosion, leading to an excavation in the central (older) part of the colony. Given suitable hydrodynamic conditions, the living tissue can grow again on the sides of the excavation. Because of its gross morphological similarity with that of an atoll (at a much smaller scale), such formations have been named “micro-atolls” (Figure 3).

Environmental factors other than emersion that control the growth rates of *Porites* include light, temperature, turbidity, and depth (which itself integrates the action of light, water motion, rates of sedimentation – see “Corals: Environmental Controls on Growth”).

In broad terms light enhances calcification, and its variations with season and depth account for some of the variability recorded in growth rates. The physiological

**Porites, Figure 3** A micro-atoll of *Porites lutea*, emerged during a low spring tide on a reef flat. Such micro-atolls can have a diameter of several meters.

and biochemical processes involved in calcification are not yet fully understood and may include a decoupling of calcification from photosynthesis and possibly an intrinsic rhythm of calcification.

Growth rates of *Porites* are significantly related to average sea surface temperature, which is one of the most important factors controlling growth rates. Lough and Barnes (2000) report that in the Indo-Pacific region, including the Hawaiian Archipelago, annual extension rates increase by 3.1  $\text{mm year}^{-1}$  for each  $1^\circ\text{C}$  increase in average annual SST, within the range  $23\text{--}29^\circ\text{C}$ . They further surmise that on the Great Barrier Reef, sensitivity of calcification rates to SST suggests that growth rates of *Porites* will – at least initially – increase as a result of global warming. There is some evidence that calcification rates did increase for much of the twentieth century, but recent findings suggest that the trend has been dampened post-1985, possibly due to a decrease in aragonite saturation levels linked to ocean acidification (De'ath et al., 2009).

As mentioned above, other factors such as depth, water motion, fine particle sedimentation, and pollutants play a role in combination in controlling growth rates of *Porites*. However, no clear picture emerges when considering, for instance, inshore–offshore gradients. Extension rates decrease with distance from shore on the Great Barrier Reef and in Thailand, but increase with distance from shore in Jakarta Bay and in Mayotte. In the latter case, however, Priess et al. (1995) also indicate a decrease in growth rates with depth on the outer slope of the barrier reef.

Through the process of calcification, corals incorporate a number of trace elements (various stable isotopes, particularly of oxygen and carbon, fulvic acids, etc.) in their skeleton throughout their lives. Their time of incorporation can be precisely determined, providing a means to characterize the environment at that time. Long-lived species such as massive *Porites*, in particular, therefore constitute an archive of past climatic and environmental

conditions that can span several centuries and are a precious tool for paleoclimatic reconstructions (e.g., McGregor and Gagan, 2003).

## Mortality

Little is known on the natural mortality of the various species of *Porites*. While some massive species can live for several centuries, the situation is very different for many other massive species that never reach large sizes, and for branching species.

Mortality can be the result of catastrophic events such as tropical storms or cyclones (see “*Tropical Cyclone/Hurricane*”). These events can bury some colonies under thick layers of sediment and dislodge others, sometimes throwing them onto the reef top or rolling them into unviable depths down the reef slope (Massel and Done, 1993). Large *Porites* colonies, if overtopped in well-illuminated habitats, rarely die completely. Partial mortality may be observed on the parts of the colonies that come into contact with the substratum, but the rest of the colony may continue to live and grow normally, even colonizing the dead part of the former under surface. Tropical storms and cyclones may be associated with freshwater runoff from flooding coastal rivers. Decrease in salinity, particularly if maintained over significant periods of time, is likely to induce a bleaching of the colonies (i.e., a breakdown of the symbiotic association), which may lead to partial or total mortality (Brown, 1997).

Extreme temperatures, particularly high SSTs at the end of the warm season are a frequent cause of coral bleaching. In general, *Porites*, particularly the large-sized species, are more resistant to extremes of temperatures than many other coral genera, e.g., *Acropora*, *Pocillopora*, *Galaxea*, or *Pavona* (Marshall and Baird, 2000). However, bleaching resulting from a temperature stress and leading to partial or total mortality has been recorded for a number of *Porites* species. There are also a number of other causes of bleaching which may affect *Porites*, in particular heavy sedimentation (or re-suspension) of fine particles, a situation commonly found in inshore reefs (see *Turbid-Zone and Terrigenous Sediment-Influenced Reefs*), and reefs affected by anthropogenic disturbances near the shore line (dredging, excavating, in-filling).

Like many other coral genera, *Porites* can be affected by natural enemies which impair the integrity of the colonies to various degrees. Infestations of boring mollusks (*Lithophaga*), sponges (*Cliona*, *Microciona*), polychaetes (*Spirobranchus*), sipunculid worms, and several species of cirripeds are known to disturb natural growth and at times modify the shape of the colonies. In many instances, however, such infestations do not lead to partial or total mortality of the colonies infested but may result (particularly in the case of cirriped infestation) in the development of a pink blotch syndrome. One specialized coral predator, the crown of thorns starfish *Acanthaster planci*, when present in large numbers, may cause up to 90% hard coral mortality in an area. *Porites*, however, generally becomes

the prey of *Acanthaster* only after most other hard coral species have been consumed. It is possible that the massive growth form with a comparatively smooth surface of *Porites* makes it less easy to be climbed on by *Acanthaster*, and the possibility of chemical defense has also been suggested (Barnes et al., 1970). Nevertheless, recurrent *A. planci* outbreaks can cause major depletions of reef-wide *Porites* populations that cannot necessarily be fully restored between outbreaks, with the potential to cause a rapid run-down of their abundances and size-structure (Done, 1988). Black band disease, due to an infection by the cyanophyte *Phormidium corallyticum*, has been reported on *Porites* spp. on the Great Barrier Reef, but its incidence remains very low, compared to that on other coral genera, most notably *Acropora*.

## Summary

The importance of the genus *Porites* on coral reefs reflects to a large extent the survivability of a handful of very environmentally tolerant species. The genus occurs in both the Atlantic and Indo-Pacific, and it is in the latter where it produces – by scleractinian coral standards – among the largest and most long-lived coral colonies. *Porites* is a predominant reef frame builder, and an excellent archive of recent past environmental conditions and climate. Longevity, resulting from its capacity to withstand natural and anthropogenic stress and impacts better than most other genera, has also brought the genus to its position of dominance. Massive colonies of *Porites* are a good example of a “long-lived species that structures coral reef systems” (Cameron and Endean, 1985).

## POROSITY VARIABILITY IN LIMESTONE SEQUENCES

Barbara H. Lidz  
 U.S. Geological Survey, St. Petersburg, FL, USA

## Synonyms

Aquifer system; Aquifer vs. aquiclude vs. aquifuge (confining bed); Fenestrate vs. non-fenestrate (non-perforate); Hydrostratigraphic unit; Karst in Florida Boulder Zone; Large voids in fossil coral reef; Porosity affects permeability (fluid flow); Small grain-supported interstitial space in rock or soil

## Definition

Porosity is the state of being porous, as measured by the percentage of bulk volume of a rock or soil that is occupied by space, whether isolated or connected. In hydrocarbon-bearing limestone settings, subsurface porous strata containing the oil or gas usually underlie non-porous caprock through which hydrocarbons cannot pass. In karst-limestone settings, subsurface freshwater aquifers beneath caprock can become contaminated by saltwater intrusion during periods of drought. Islands of the Florida Keys consist of two types of emergent 125-ka limestone, a highly porous fossil coral reef with

**Porosity Variability In Limestone Sequences, Figure 1** (a) Core slab from the Saddlebunch Keys (lower Florida Keys) shows thick calcrete unconformity on top of Miami Limestone oolite. (b) Cut rock sample from the Key Largo Waterway on Key Largo (upper Florida Keys) shows the same calcrete unconformity as it developed on top of Key Largo Limestone coral reef (reprinted from Lidz et al., 2007, with permission). This figure (a and b) is also cited in the Definition and figure caption for the entry entitled, Calcrete/Caliche. See Figure 2a in entry entitled, Florida Keys, for locations of the Saddlebunch Keys and the Key Largo Waterway.

large voids and a less porous oolite with small grains and interstices. Both limestones are capped by impervious laminated Holocene calcrete whose dimensions differ greatly (Figure 1a and b). Porosity variability in the limestones is thought to be the cause. The less permeable oolite retained rainfall moisture longer, allowing longer periods of calcrete buildup. Reddish and brownish layers in both illustrated calcrete samples represent periods of influx of non-carbonate minerals on African dust. The hiatus or gap in these rock records represents an interval of >115 kyr during which no marine or terrestrial deposition is recorded.

## POSTGLACIAL TRANSGRESSION

Guy Cabioch  
 IRD (Institut de Recherche pour le Développement),  
 Bondy CEDEX, France

### Synonyms

(Last) Deglacial sea-level rise; Post glacial sea-level rise

### Definition

The post-glacial transgression is the rise in sea level from –120/130 m to present position in the period 19–6/5 kyears, and caused by global glacial melting.

### Reef growth mode, tectonic and reconstruction of sea-level variations

The corals are reliable markers of sea level (see entry [Sea-level Indicators](#)) and several curves of the deglacial

sea level were proposed using their dating (see entry *Uranium Series Dating*). The reconstruction of these curves must take into account several parameters including the reef-growth patterns and the tectonic parameters (rate of vertical motions).

The mode of reef growth must be examined with accuracy because the organisms respond differentially to more or less rapid sea-level rise (see entries *Corals: Environmental Controls on Growth* and *Sea Level Change and Its Effect on Reef Growth*). Moreover, the corals can have a broad living bathymetric range. Three growth mode strategies were defined by Neumann and Macintyre (1985) and Davies and Montaggioni (1985): (1) the “keep-up” growth mode strategy characterizes the reefs able to maintain pace with sea-level rise, composed of relatively shallow-water and high-wave energy organisms; (2) the “catch-up” growth mode strategy characterizes the reefs, which were not initially able to keep pace with sea-level rise, but caught up as or after stabilizations of the sea level. The communities are made of relatively deeper, less wave-resistant and less light-intensity organisms, progressively replaced upwards by relatively shallow-water and high-wave energy resistant organisms; (3) the “give-up” mode strategy, the organisms are not able to compensate the sea-level rise and gradually drowned.

The corrections due to the tectonic parameters must also be taken into account. The uplift rate in the island arc sites and the subsidence in the intra-plate sites or in the continental margins, must be used to correct the sea-level curves. Moreover, the correction due to the loading of the ocean floor by the meltwater (hydro-isostatic effects) should also be taken into account (see Lambeck et al., 2002).

### The sea-level curves from the last deglacial rise

Corals can be used to reconstruct entirely or partly the deglacial sea-level rise curves. Several areas were investigated in the uplifted sites (island arcs) from Barbados (from 22.1 to 7.4 ka, 1 ka = 1,000 years (Fairbanks, 1989; Bard et al., 1990; Peltier and Fairbanks, 2006) and Papua New Guinea (Cutler et al., 2003 and from 13.1 to 8.3 ka, see Edwards et al., 1993) and in the subsiding site of Tahiti in French Polynesia (from 13.8 to 2.8 ka, Bard et al., 1996, 2010, Figure 1). Additional data are available in South-West Pacific in Vanuatu (from 22.6 to 6.6 ka, Cabioch et al., 2003) and in North-West Pacific in the Ryukyus (Sasaki et al., 2006). In the first curve using coral dating presented by Fairbanks (1989), two episodes of Meltwater Pulses (MWP) were identified, the MWP 1A at around 14 ka and the MWP 1B at 11.3 ka. Although these events will be presented in the entry “*Meltwater Pulses*”, a short description is also given below.

### Episodes of rapid sea-level rise

During the last deglacial sea-level rise, several episodes of rapid rise occur. The existence, the timing, the magnitude, and the cause of some of these sharp rises are however still

**Postglacial Transgression, Figure 1** Sea level curves deduced from the coral dating in Barbados and Tahiti (Modified after Bard et al., 1996).

debated. Three episodes have been proposed: the 19 ka event, the MWP 1A, and the MWP 1B. Some of these episodes were attributed to episodes of Meltwater Pulses (MWP, see Chapter *Meltwater Pulses*), but the source needs to be clearly identified. According to some authors, an additional event should also be considered at around 7.5 ka (Blanchon et al., 2002; Yu et al., 2007; Siddall et al., 2010).

### The 19 ka event

The 19 ka event defined in the Bonaparte Gulf (Australia) by Yokoyama et al. (2000), at the end of the Last Glacial Maximum (LGM) is characterized by a rapid sea-level rise of 10–15 m. Clark et al. (2004) confirm the occurrence at 19 ka of a rapid 10-m-sea-level rise deduced from the sediment analyses of the Irish Sea. Drowning of reefs in the Marquesas (Cabioch et al., 2008) at this time adds further support to such an event. The cause of this 19 ka event is attributed by Clark et al. (2004) to the melting of at least one Northern Hemisphere ice sheet but this needs to be constrained by further geochronological data (Clark, 2009).

### The MWP 1A

The second event at 14.5 ka is marked by a rapid sea-level rise of 20 m in less than 500 years. It is reported at various sites but the timing and the source are also still actively debated. Fairbanks (1989) first reported this event in the Barbados, but it is also observed in numerous sites from the Pacific and Atlantic Oceans. In the Sunda shelf, the sea level increased rapidly by 16 m from 14.6 to 14.3 ka. An apparent discrepancy in the timing of the MWP 1A between Barbados (Fairbanks, 1989; Bard et al., 1990; Peltier and Fairbanks, 2006), Papua New Guinea (Cutler et al., 2003), and Bonaparte Sea (Yokoyama et al., 2000) reported in Stanford et al. (2006) is probably due to the fact that the living bathymetric range of dated corals was

not taken into account to correct the sea-level curve (Clark, 2009). The reef growth mode needs always to be considered. Nevertheless, Peltier and Fairbanks (2006) highlight the fit between the record from Barbados and Sunda shelf. The possible sources of the MWP 1A are also highly debated. The ice melting from Northern Hemisphere is probably accompanied by a contribution of the Antarctica (Clark, 2009), although Peltier and Fairbanks (2006) consider that Antarctica is not a significant contributor of the source of the MWP 1A. All these discussions emphasize the need to acquire new data to improve the interpretations and the models.

In addition to the study of living reefs, studies of drowned reefs also sheds light on the MWP-1A event. In Hawaii, the drowning of the 150-m-coral reefs, constrained by its datation from 15.2 to 14.7 ka, is interpreted by Webster et al. (2004) as caused by the rapid sea-level rise of the MWP 1A. Similar observations can be made in the Marquesas archipelago, the drowning of the coral reefs ranging from 110 to 95 m and dated from 16.2 to 14.5 ka (Cabioch et al., 2008) can be also a consequence of the rapid sea-level rise of the MWP 1A. Similar sites of drowned reefs can be observed in various regions but at this day, no dates were performed and we cannot conclude on the causes of the drowning.

### The MW 1B

The MWP 1B was defined in Barbados by Fairbanks (1989). Nevertheless, the existence of such an event is still debated and discussed. Recently, Peltier and Fairbanks (2006) indicated that the source from Antarctica of the MWP 1B is assumed by the model ICE-nG. Although the timing and the magnitude of the MWP 1B cannot be confirmed by the observations of the deglacial sea-level curves from Papua New Guinea (West Pacific) and Tahiti (South Pacific), this event seems to be recognizable in the West Pacific in Vanuatu (Cabioch et al., 2003) and in the Indian Ocean in Mayotte island (Zinke et al., 2003). Although the magnitude of the MWP 1B, if real, seems to be smaller than in the MWP 1A, significant changes can be observed in reef growth patterns in Vanuatu at this period (Cabioch et al., 2003): it appears that around 11.5 ka, relatively shallow-water communities were replaced by relatively deeper organisms, that is, the reef was not able to maintain pace with sea-level rise and the water depth strongly increased over the reef. Similarly, in the Marquesas archipelago, reefs at depths between 80 and 68 m and dated at around 12.4 ka seem to have been drowned (Cabioch et al., 2008). However, the existence of this event is still discussed and debated because most of coral reefs continued to grow during this period as for example in Tahiti (Bard et al., 1996). New uranium-thorium dates were recently obtained on corals from Tahiti providing a new Tahiti sea-level record (Bard et al., 2010). This new record points out no significant change in the sea-level rise during the period attributed to the MW 1B, but a slower rate of sea-level rise during the Younger Dryas (11.6–12.9 ka).

### The 7.5 ka event

In 2002, Blanchon et al. reported the occurrence of a 6-m-rapid jump of the sea level at around 7.5 ka. Such an event at this period is rarely reported (Yu et al., 2007) and needs to be validated but many modern coral reefs settled after this date, especially in the Pacific (Montaggioni, 2005). Additional data must be collected regarding the occurrence of this event.

### Prospects

In 2006, in the framework of the international program IODP (Integrated Ocean Drilling Program), the Tahiti Sea Level Expedition 310 was conducted by G. Camoin, Y. Iryu, and D. McInroy in Tahiti to improve our knowledge on the last deglacial sea-level rise, to analyze the SST changes during this period, and to define the reef development controlled by these two last factors (Camoin et al., 2007). Several cores were collected in 22 sites from three areas. One of the objectives of this expedition was to define the sea-level variations over the period from 20 to 10 ka. At this day, the results are not yet published but the data probably will improve our knowledge on the timing and the sources of the MWP. Another IODP expedition is currently in progress in the Australian Great Barrier Reef (Expedition 325) focused on similar topics, that is, to analyze the pattern of the last deglacial sea-level rise far from the polar sites and to provide data to solve the timing and the magnitude of the brief and rapid increases of sea-level rise (Webster et al., 2009).

### Summary

The postglacial transgression is of broad interest, interacting with the reef growth patterns and the history of the reef development. The last sea-level rise is marked by episodes of rapid increase. Some of them are clearly attributed to melt water pulses but the timing, the magnitude, and the melting source are still debated and discussed. Additional data in sites tectonically stable and far from the polar sites are required to solve these questions. The corals and the coral reefs are reliable contributors and the key to reconstruct with accuracy the last deglacial sea-level curves, the timing and magnitude of the brief and rapid episodes of sea-level rise on condition that the bathymetric range of coral dated can be estimated and the reef growth mode defined.

## QUOY, JEAN RENE (1790–1869) AND GAIMARD, JOSEPH PAUL (1796–1858)

---

James Bowen  
Southern Cross University, Lismore, NSW, Australia

Following the Napoleonic Wars, further scientific investigation of the southern oceans by the competitive powers of England and France resumed, although the French expedition 1800–1804 under Baudin in command of *Le Géographe* and *Naturaliste* was a fiasco marred by scurvy of his crew and conflict with the naturalist François Auguste Péron. Since the British were making important gains in the south Pacific the French renewed their interests and in September 1817 *L' Uranie* under the command of Louis Claude Desaulles de Freycinet sailed from Toulon, carrying aboard surgeon and zoologist Dr. Jean René Constand Quoy and assistant surgeon and zoologist Joseph Paul Gaimard who were to make significant contributions to helping solve the puzzle of atoll and coral reef formation in the otherwise great open spaces of the tropic oceans.

By the early nineteenth century, reef atoll formation was known to have come from small animal polyps, but many other questions, however, remained unanswered. Given the enormous depth of the surrounding waters, unable to be sounded by the technology of the times, how had polyps established themselves in the first place? Upon what foundations had they erected their limestone structures? What was the nature of that “instinct” proposed by Forster by which “the animalcules forming these reefs... shelter their habitation from the impetuosity of the winds?” Most importantly, why were the atolls circular in shape – many being miles in diameter – readily confirmed from the crow’s-nest of the exploring ships?

In that period of extensive reef investigation from 1817 to 1820, chiefly to the Mariana, Hawaiian and Dutch East

Indies island groups, the two zoologists offered an explanation from their findings in 1824 entitled *Mémoire sur l'Accroissement des polypes lithophytes considéré géologiquement* (“Geological aspects of coral formation”). In that joint paper they argued from their extensive examination of reefs in Pacific tropical waters that it would be a mistake to ascribe all atoll formation to polyps alone, growing up from the ocean floor. Rather, they believed that coral reefs are surface features that have as a base the same element, the same minerals which concur to form all the known islands and continents... that [in effect] they build their dwellings on the submarine rocks, enveloping them entirely, or in part, but properly speaking they do not form them. Thus, all these reefs, they concluded, “are, in our opinion, platforms arising from the conformation of the primitive surface.”

Tragically, on the return voyage approaching Patagonia *L' Uranie* was wrecked on an uncharted reef, and although the ship was beached, their supplies and a large part of their natural history specimens were lost as the violent seas rapidly destroyed the foundering vessel. Eventually, however, they were rescued by a passing American vessel which carried them and their scientific specimens to Montevideo from where, when they arrived in France their specimens – mammals, birds, fish and insects – were received by the Academy of Sciences with considerable admiration. What created intense interest were the jars of preserved marine creatures, particularly polyps and invertebrates, and the drawings made by the artists and naturalists of the expedition.

In 1826 Quoy and Gaimard were to sail again on a voyage of exploration to the south Pacific aboard the frigate *L' Astrolabe* under the command of Jules Sébastien César Dumont d'Urville where they were able to continue their observations on coral formations and the taxonomic distinction between those described by Peyssonnel as “supple and pliant” and “stony, hard, inflexible”.

## RADIOCARBON ( $^{14}\text{C}$ ): DATING AND CORALS

---

Stewart Fallon

Australian National University, Canberra, ACT, Australia

### Definition

Radiocarbon or  $^{14}\text{C}$  is the radioactive isotope of carbon. It is the basis for radiocarbon dating and is useful for dating materials that contain carbon back in time to around 50,000 years ago.

### Introduction

There are three *isotopes* of carbon found in nature. They are carbon-12, carbon-13, and carbon-14. Carbon-12 accounts for  $\sim 99.8\%$  of all carbon atoms, carbon-13 accounts for  $\sim 1\%$  of carbon atoms while  $\sim 1$  in every 1 billion carbon atoms is carbon-14. Hereafter, these isotopes will be referred to as  $^{12}\text{C}$ ,  $^{13}\text{C}$ , and  $^{14}\text{C}$ .  $^{14}\text{C}$  is radioactive and has a *half-life* of 5,730 years. The half-life is the time taken for an amount of a radioactive isotope to decay to half its original value. Because this decay is constant it can be used as a “clock” to measure elapsed time assuming the starting amount is known. A unique characteristic of  $^{14}\text{C}$  is that it is constantly formed in the atmosphere (Figure 1).

### Production and decay

$^{14}\text{C}$  atoms are produced in the upper atmosphere where neutrons from cosmic rays knock a proton from nitrogen-14 atoms. These newly formed  $^{14}\text{C}$  atoms rapidly oxidize to form  $^{14}\text{CO}_2$ . They are chemically indistinguishable from  $^{12}\text{CO}_2$  and  $^{13}\text{CO}_2$ . They then join the earth's carbon cycle. Plants incorporate  $^{14}\text{C}$  during photosynthesis and organisms that eat plants take up this  $^{14}\text{C}$ .  $^{14}\text{C}$  gets into the dissolved inorganic carbon pool in the oceans, lakes, and rivers. From there it gets into shell,

corals, and other marine organisms. When a plant or an animal dies, it no longer exchanges  $\text{CO}_2$  with the atmosphere (ceases to take  $^{14}\text{C}$  into its being). This starts the radioactive decay “clock.”  $^{14}\text{C}$  decays by emitting an electron, which converts a neutron to a proton, converting it back to its original  $^{14}\text{N}$  form.

### History of radiocarbon dating

Willard Libby invented radiocarbon dating in the late 1940s. This invention revolutionized science as a means to provide ages to events over the past  $\sim 50,000$  years. Libby was awarded the Nobel Prize for chemistry for this contribution. His first publication showed the comparisons between known age samples and radiocarbon age (Libby et al., 1949; Libby, 1952).

### Measuring $^{14}\text{C}$

To obtain the radiocarbon age of a sample one must determine the proportion of  $^{14}\text{C}$  it contains. Originally, this was done by what is known as “conventional” methods, either proportional gas counters or liquid scintillation counters. The gas counter detects the decaying beta particles from a carbon sample that has been converted to a gas ( $\text{CO}_2$ , methane, and acetylene). A liquid scintillation measurement needs the carbon to be converted into benzene, the instrument then measures the flashes of light (scintillations) as the beta particles interact with a phosphor in the benzene. The main limitation of these techniques is sample size, and hundreds of grams of carbon are needed to count enough decaying beta particles. This is especially true for old samples with low beta activity. In the late 1970s and early 1980s, the dating of small samples became possible using accelerator mass spectrometry (AMS; Muller, 1977; Nelson et al., 1977). This method needs less than 1 mg of carbon and directly measures the abundance of the individual ions of carbon ( $^{14}\text{C}$ ,  $^{12}\text{C}$ , and  $^{13}\text{C}$ ).

To obtain a radiocarbon age the sample activity or the  $^{14}\text{C}/^{12}\text{C}$  ratio must be compared to a standard material of known age. All radiocarbon laboratories either standardize to the US National Bureau of Standards Oxalic Acid I (OX-I), which is derived from Sugar Beets in grown in 1955 or a secondary standard NBS OX-II (grown in 1977) or Australian National University Sucrose (ANU), which is sugar from the 1974 sugar cane growing season in Australia. Both the OX-II and ANU have been extensively cross calibrated to OX-I and can be used to normalize a sample for radiocarbon dating. The absolute radiocarbon standard is 1890 wood, the OX-I standard has an activity of 0.95 of this wood. The definition of year “0,” “modern” or “present” is 1950, there is no real reason for this other than to commemorate the publication of the first radiocarbon dates.

The radiocarbon age is determined by the equation

$$t = -8,033 \ln(\text{Asn}/\text{Aon})$$

where  $-8,033$  represents the mean lifetime of  $^{14}\text{C}$  (Stuiver and Polach, 1977), Asn is the activity in counts per minute of the sample, and Aon is the counts per minute of the modern standard. A variant of this equation is also used when

the samples are analyzed by AMS. All radiocarbon ages are normalized to a  $\delta^{13}\text{C}$  of  $-25\text{‰}$  relative to Pee Dee Belemnite (PDB).

### Calibration to time

In the 1950s, it was observed that the radiocarbon time-scale was not perfect. The age of known artefacts from Egypt were too young when measured by radiocarbon dating. A scientist from the Netherlands (Hessel de Vries) tested this by radiocarbon dating tree rings of known ages (de Vries, 1958). He noted some discrepancies indicating that radiocarbon results would need to be “calibrated” to convert them to calendar ages. de Vries also postulated that the fluctuations were due to the production of  $^{14}\text{C}$  and how it changed during variations in cosmic ray production. This brings us to two reasons why a radiocarbon date is not a true calendar age. The true half-life of  $^{14}\text{C}$  is 5,730 years and not the originally measured 5,568 years used in the radiocarbon age calculation, and the proportion of  $^{14}\text{C}$  in the atmosphere is not consistent through time. The latter is due in part to fluctuations in the cosmic ray flux into our atmosphere (e.g., sunspot activity). Since then there have been many studies examining the

**Radiocarbon ( $^{14}\text{C}$ ): Dating and Corals, Figure 1** Schematic of  $^{14}\text{C}$  production and decay in the atmosphere.  $^{14}\text{C}$  is produced in the atmosphere by cosmic neutrons colliding with Nitrogen atoms. The newly formed  $^{14}\text{C}$  is oxidized to  $^{14}\text{CO}_2$  where it then enters the biosphere. Following an organism's death, radioactive decay occurs converting the  $^{14}\text{C}$  back to  $^{14}\text{N}$ .

variations in the  $^{14}\text{C}$  production and its effects on the radiocarbon age to calendar age calibration (e.g., Stuiver, 1971; Edwards et al., 1993; Kitagawa and Van de Plicht, 1998; Stuiver et al., 1998; Fairbanks et al., 2005). The proportional amount of  $^{14}\text{C}$  to total carbon has also changed during the industrial revolution ( $\sim 1890$ ). Since fossil fuel is derived from millions of year old organic carbon, it contains no  $^{14}\text{C}$ . The burning of fossil fuels has caused a dilution of  $^{14}\text{C}$  in the atmosphere, this is the so-called Suess effect named after Hans Suess (Suess, 1965, 1980).

It is essential to have radiocarbon ages calibrated to calendar ages so as to have an accurate measure of time. It is also important to be able to compare ages with samples dated by other means, for example, uranium-series dating. It therefore became necessary to create a calibration between radiocarbon dates and calendar age. The ideal calibration material must have a precise calendar age and sample the atmosphere (carbon reservoir of interest).

### Tree-ring calibration

Fortunately, there is a suitable calibration material available in nature and this is called annual tree rings. Since those first measurements in the 1950s a detailed, precise calibration between radiocarbon and calendar age has been developed using many long-lived tree species. Dendrochronology provides the accurate calendar age for each ring in the tree, and then a radiocarbon age can be assigned to each calendar age. Several tree-ring chronologies have been constructed including the Belfast Irish Oak chronology (Baillie et al., 1983; Brown et al., 1986) back to  $\sim 7,200$  years and the Stuttgart–Hohenheim oak and pine chronology (e.g., Friedrich et al., 2004; Schaub et al., 2008; Hua et al., 2009) back to  $\sim 12,594$  years using thousands of accurately dated tree rings. However this is as far back in time as the continuous tree-ring radiocarbon calibration can be extended at present. More old trees are being discovered every year and this may eventually increase this calibration dataset at a later date. There are also a number of “floating” tree-ring chronologies that are being developed. They are called floating because they do not have a direct calendar age and must use the radiocarbon to match their ages. Many sections of old subfossil New Zealand Kauri trees have been found that span time from 25 to 60,000 years old (Hogg et al., 2006; Turney et al., 2007).

In order to extend the calibration curve back to 50,000 years other archives have been targeted, these include Foraminifera preserved in continuous annually laminated (varved) sediments (e.g., Kitagawa and van der Plicht, 2000; Hughen et al., 2004), tropical surface corals (e.g., Bard et al., 1998; Burr et al., 1996, 2009; Cutler et al., 2004; Fairbanks et al., 2005; Chiu et al., 2007), and speleothems (e.g., Beck et al., 2001; Genty et al., 1999). These additional archives extract their carbon from the dissolved inorganic carbon surrounding them and not directly from the atmosphere. But the carbon is closely linked to the atmosphere and can be corrected for this

offset. Both fossil corals and speleothems can be precisely dated to a calendar age by uranium-series dating and therefore can be used in extending the radiocarbon calibration curve. Beyond the tree-ring calibration, fossil corals and Foraminifera from Cariaco Basin and the Iberian Margin make up the calendar age to radiocarbon age calibration (Figure 2).

### Calibration curves

Over the last 20 or so years there have been several calibration “curves” ratified by the Radiocarbon International Community (IntCal98, IntCal04, IntCal09; Stuiver et al., 1998; Reimer et al., 2004; McCormac et al., 2004; Reimer et al., 2009), there have also been other calibration curves proposed by individual research groups (e.g., Fairbanks et al., 2005). Figure 2 shows the most recent IntCal09 calibration curve superimposed over many of the coral and foram varve archives. These calibration curves form the basis of several online calibration programs that take the radiocarbon age and output a calibrated age, the four major online calibration programs are the following:

Calib – <http://intcal.qub.ac.uk/calib/>

CalPal – <http://www.calpal.de/>

OxCal – <http://c14.arch.ox.ac.uk/embed.php?File=oxcal.html>

Fairbanks – <http://radiocarbon.ldeo.columbia.edu/research/radcarbcal.htm>

### Radiocarbon in the ocean

Marine organisms have a further complication when it comes to radiocarbon dating. The exchange between the ocean and atmospheric  $^{14}\text{CO}_2$  takes on average 10 years to come into equilibrium (Broecker et al., 1985), which never completely happens. Because the reservoir of carbon in the ocean is so vast and the mixing between the surface and deep ocean is sufficiently long, radioactive decay of carbon in the ocean occurs. The deep ocean can have an apparent age of several thousand years. This old carbon mixes upward by a process called “upwelling.” Amounts of upwelling vary throughout the oceans of the world. This results in the surface ocean having an average apparent age of  $\sim 400$  years although there is considerable variability. This is called the reservoir age or reservoir effect (e.g., Druffel et al., 2008; Eiriksson et al., 2004; Franke et al., 2008). Marine shells of known age collected prior to 1955 and independently dated corals have been used to measure this reservoir variability (e.g., Bourke and Hua, 2009; Cullen et al., 2006; Petchy et al., 2009). Online databases are available to estimate the reservoir age of a marine sample (Reimer and Reimer, 2009 <http://calib.org/marine>; Butzin et al., 2005; <http://radiocarbon.ldeo.columbia.edu/research/resage.htm>). This is then used to adjust the radiocarbon age and calibrate to a calendar age. A full marine calibration curve is also available (Marine04, Marine09) to calibrate a marine radiocarbon age, it was calculated using an ocean-atmosphere box

**Radiocarbon ( $^{14}\text{C}$ ): Dating and Corals, Figure 2** Radiocarbon calibration figure, conventional radiocarbon age on the y-axis vs. Calendar age on the x-axis. The IntCal09 dataset is used back to 50,000 years BP comprises tree-ring data, (Reimer et al., 2009, red line), corals from various locations can also be used to constrain this calibration. Shown here is corals data from Barbados (blue square), Kirimati (green triangle), and Araki (purple diamond) from Fairbanks et al. (2005). Also shown are Foraminifera from Cariaco Basin in the thin line (Hughen et al., 2006).

diffusion model for the time period 0–10,500 years (Oeschger et al., 1975; Stuiver and Braziunas, 1993) and foram and coral data from 10,500 to 12,500 years as described in Hughen et al. (2004). Beyond 12,500 years, the atmospheric calibration curve is used with a constant reservoir age of 405 years (Reimer et al., 2009).

#### “Bomb” radiocarbon

During the 1950s and 1960s, nuclear weapons testing generated excess neutrons in the atmosphere thereby creating manmade  $^{14}\text{C}$ . This production ceased in 1963 with the signing of the nuclear test ban treaty, however not before the  $^{14}\text{C}/\text{C}$  ratio in the atmosphere nearly doubled. This “bomb” radiocarbon has been used to help understand the uptake of  $\text{CO}_2$  by the ocean and by the terrestrial biosphere. The subsequent invasion of this “Bomb”  $^{14}\text{C}$  into the surface ocean has increased the radiocarbon difference between the surface and the deep ocean (e.g., Broecker, et al., 1985). The use of  $^{14}\text{C}$  as a global ocean circulation tracer was a primary objective of the study of the distribution of natural and bomb-produced  $^{14}\text{C}$  in the Geochemical Ocean Sections Study (GEOSECS) of the early 1970s (Ostlund and Stuiver, 1980; Broecker et al., 1985) and of the present-day World Ocean Circulation Experiment (WOCE; Key et al., 1996). The GEOSECS data identified a surface water gradient of post-bomb  $^{14}\text{C}$  from the equator toward the temperate latitudes. Broecker and Peng (1982) interpreted this distribution as representing

upwelling of low  $^{14}\text{C}$  water from the lower thermocline in equatorial regions, with migration of the  $^{14}\text{C}$  rich surface water toward higher latitudes.

Radiocarbon measurements of coral skeletal material have been used to study how the radiocarbon content of the tropical surface ocean has varied through time (e.g., Druffel 1981; Guilderson et al., 2000, 2009). Many coral genera construct massive colonies often 200–400 years old, which in shallow reef environments have growth rates on the order of  $1 \text{ cm year}^{-1}$ . Because the radiocarbon in the coral aragonite skeleton reflects seawater radiocarbon content at the time of deposition, radiocarbon measurements across annual skeletal density bands in such corals make it possible to reconstruct the annual mean radiocarbon content of the surface ocean back to pre-bomb and preindustrial values

#### Summary

Radiocarbon is a useful means for obtaining the age of death of a carbon-bearing organism. With the help of international scientists, a robust calibration has been developed back to 50,000 years ago. Annual tree rings provide the calibration back to  $\sim 12,594$  year BP and corals and forams helped refine this calibration back to 50,000 years ago using uranium-series dating in conjunction with radiocarbon dating. Corals have also played a role in trying to understand the oceanic uptake of  $\text{CO}_2$  and for tracking ocean currents and circulation.

## RECENT SEA LEVEL TRENDS

Philip L. Woodworth

National Oceanography Centre Liverpool, Liverpool, UK

## Synonyms

Sea level; Sea surface height; Still water level

## Definitions

**Sea level.** Height of the sea relative to the height of a benchmark on the nearby land (in tide gauge data analysis). Height of the sea relative to a reference surface such as an ellipsoid or geoid (in altimeter data analysis).

**Mean sea level.** Sea level averaged over a period of time, such as a month or year, long enough that fluctuations caused by waves and tides are largely removed (in tide gauge data analysis).

**Still water level.** The sea level that results from ocean processes including tides, surges, and mean sea level changes but not including waves.

**Sea surface height.** A term synonymous with “sea level” but used mostly in altimeter data analysis.

**Sea level trends.** Rates of change of sea level over a stated period either for a given location or averaged over a region or the global ocean.

## Introduction

Sea levels have been measured with what are usually called “tide gauges” for many hundreds of years, both for practical purposes, such as efficient operation of a harbor, or for scientific research. For example, the first extended set of sea level measurements in the UK comprised heights and times of high water at Liverpool during 1764–1793 recorded by William Hutchinson (Woodworth, 1999). By the 1830s, the automatic tide gauge had been developed, consisting of a float in a stilling well and with the float’s motion recorded on a paper chart. The credit for this development is often given to Palmer following his installation of a gauge at Sheerness, UK in 1832 (Pugh, 1987). In the 1970s, the first satellite radar altimeters were launched. Altimeters record the propagation time of radar pulses transmitted

from the satellite, reflected off the ocean, and received back at the satellite. Sea levels can be measured by this means with an accuracy of several centimeters and on a near-global basis (Fu and Cazenave, 2001). This technique attained optimal reliability and accuracy with the deployment of the TOPEX/POSEIDON (T/P) mission in 1992. Since that time, the community has had near-continuous availability of precise altimeter data from T/P and JASON-1 and -2, complemented by data sets from the lower-flying ERS-1 and -2 and ENVISAT satellites. Tide gauges and altimeters have together demonstrated that sea levels change over many different temporal and spatial scales.

### Recent sea level trends

Since the last ice age around 20,000 years ago, mean sea level (MSL) has risen worldwide by more than 120 m. Over the last few millennia, the rate of rise has been no more than a few tenths of mm/year. However, an acceleration appears to have taken place between the eighteenth and nineteenth centuries and into the twentieth century, based on the small number of available long European tide gauge records (Woodworth, 1999; Jevrejeva et al., 2008) and on complementary data from salt marshes (e.g., Gehrels et al., 2006). A consensus has emerged that the twentieth century rise in global sea level was closer to 2 than 1 mm/year, with values around 1.7 mm/year having been obtained recently for the past century (Cazenave and Nerem, 2004; Church and White, 2006) or past half-century (Church et al., 2004; Holgate and Woodworth, 2004). However, the rate of change was far from constant, with an acceleration around 1920–1930, a deceleration after 1960, and a relatively recent acceleration in the late 1980s or early 1990s (e.g., Woodworth et al., 2009; Douglas, 2008; Merrifield et al., 2009). The high rate in the latter period of over 3 mm/year was observed not only by tide gauges but also by satellite altimetry (Beckley et al., 2007). It has been suggested this high rate may be connected partly with a sea level recovery that started in the mid-1980s following a sea level fall after the El Chichón volcanic eruption (Domingues et al., 2008).

Figure 1 presents findings on global sea level rise by different authors, and there is general agreement between them. However, it must always be kept in mind that our knowledge of recent change is based largely on a sparse data set, that of the Permanent Service for Mean Sea Level (PSMSL) (Woodworth and Player, 2003), and that there can be considerable spatial and temporal variability in sea level change (cf. Figure 1 of Wunsch et al., 2007 for a demonstration of spatial variability in trends since the early 1990s). Sea level time series at particular locations, including coral islands, can be found in individual reports (e.g., Woodworth, 2005) and from the PSMSL web site [www.psmsl.org](http://www.psmsl.org). Vertical land movements (VLMs) due to glacial isostatic adjustment (GIA), tectonic or anthropogenic processes can play important roles in the sea level changes observed by tide gauges and by other in situ

**Recent Sea Level Trends, Figure 1** Global sea levels from three recent studies, all based on MSL data from the PSMSL. Note the higher rates of rise after 1930 and in recent years. Values denoted Church and White (2009) are updated from those reported in Church and White (2006).

techniques. VLMs due to GIA can be estimated with the use of geodynamic models (e.g., Peltier, 2001), while advanced geodetic techniques (notably Global Positioning System and Absolute Gravity) are being developed to monitor VLMs, of whatever origin, at tide gauge sites (Woodworth, 2006).

### Understanding the observed sea level rise

MSL is often described as an “integral parameter”, providing an integration of sea level changes resulting from many climate-change related processes over many years, of which oceanic thermal expansion, melting of glaciers, ice caps and ice sheets, and modifications to hydrological exchanges between land and ocean are the most important. Consequently, if MSL is changing, it points to major changes in one or more of the climate-related drivers of that change. Ice sheets have the potential to raise sea level by far more than the other processes (see Table 11.3 of Church et al., 2001), although their contribution during the past century appears to have been small.

The composition of the various contributions to sea level change (the “sea level budget”) forms a major research topic which is addressed regularly in the scientific assessments of the Intergovernmental Panel on Climate Change (IPCC), the most recent being the Third Assessment Report (TAR) (Church et al., 2001) and Fourth Assessment Report (AR4) (Bindoff et al., 2007). Figure 2 summarizes the budget calculated by the AR4. The inability of these assessments to account for most of the observed rise (the “sea level enigma” of

**Recent Sea Level Trends, Figure 2** Contributions to sea level rise (upper four entries), their sum, and the observed rates of sea level rise for 1961–2003 (red) and 1993–2003 (blue). The bars represent the uncertainty range. The difference (Obs – Sum) represents the “sea level enigma.” For details, see Bindoff et al. (2007).

Munk, 2002) has to some extent been resolved, at least for recent decades, by a reworking of hydrographic data sets and through the availability of more complete space and in situ instrumentation for the determination of thermal expansion (Domingues et al., 2008). At the time of writing, “budget estimates” for the last decade, during which the community has had available information from satellite gravity [i.e., the Gravity Recovery And Climate Experiment (GRACE) mission] and Argo hydrography in addition to altimeter and tide gauge data, have been more consistent, although discrepancies remain (Willis et al., 2008; Cazenave et al., 2009). One is confident that consensus will eventually be achieved as global observation systems become more complete.

Reviews of the field have been undertaken by individual scientists (e.g., Cazenave and Nerem, 2004; Woodworth, 2006) and national and international study groups in between the IPCC assessments. One such major review of the status of research was undertaken by the World Climate Research Program (WCRP) in 2006 (Church et al., 2007) from which full reports on each sector of the field will be published in book form in 2010 (Church et al., 2010). One chapter is concerned with the use of sea level information derived from coral reefs, in addition to salt marsh and other coastal geological data, as a complement to and extension back in time of the instrumental record (Lambeck et al., 2010).

### Changes in extreme sea levels

As extreme sea level events often result in flooding and loss of life, an important question is whether their amplitudes and frequencies are changing, and if the levels of extreme high waters are changing in a significantly different way to MSLs. The only study which has attempted a quasi-global investigation of this topic is that of Woodworth and Blackman (2004) who studied data from 141 stations, and concluded that there is indeed evidence for an increase in extreme high water levels worldwide since 1975, as reported frequently in the press. However, in most cases, the secular changes and the interannual variability in the extremes were found to be similar to those in MSL. A number of other studies of sea level extremes at particular locations are available, although as they are for different epochs and use different methods, it is difficult to arrive at general conclusions. A review of these studies and of the meteorological forcing factors which result in extreme levels has been provided by Lowe et al. (2010).

### Predictions of future sea level trends

The IPCC assessments also provide regular updates on future sea level rise predictions based on climate modeling. The TAR projected a global averaged sea level rise of between 20 and 70 cm between 1990 and 2100 using

the full range of IPCC greenhouse gas scenarios and a range of climate models. When an additional uncertainty for land-ice changes was included, the full range of projected sea level rise was 9–88 cm. For the IPCC AR4 (Meehl et al., 2007), the range of sea level projections using a larger range of models was 18–59 cm (90% confidence limits) over the period from 1980–1999 to 2090–2099. The largest contribution was from ocean thermal expansion with the next largest contribution from glaciers and ice caps. However, there is increasing concern about the stability of ice sheets, and recognizing this deficiency, the AR4 increased the upper limit of the projected sea level rise by 10–20 cm, implying an overall range of projected sea level rise of 18–79 cm. It is unclear what confidence intervals to assign to this range given the ice sheet uncertainties. Note that they also stated that “larger values cannot be excluded, but understanding of these effects is too limited to assess their likelihood or provide a best estimate or an upper bound for sea level rise.”

While the 2001 and 2007 IPCC projections are somewhat different in how they treat ice sheet uncertainties and the confidence limits quoted, a comparison of the projections (Figure 6 of Church et al., 2008) shows the end results are similar, except that the lower limit of the 2001 projections has been raised from 9 cm in the TAR to 18 cm in the AR4.

Despite the additional allowance for ice sheet uncertainties, a number of scientists remain concerned that the ice-sheet contributions in the AR4 may have been underestimated, and they adopt a more phenomenological approach to estimating future sea level rise. For example, Rahmstorf (2007) developed a simple statistical model that related twentieth century surface temperature change to twentieth century sea level change. Using this relationship and projected surface temperature increases, he estimated that twenty-first century sea level rise might exceed the IPCC projections and be as much as 1.4 m. Holgate et al. (2007) raised concerns that Rahmstorf’s model is too simplistic and may not adequately represent future change. Similar conclusions, that the AR4 sea level rise predictions may have been underestimated have been based on analysis of longer term temperature and sea level information (Grinsted et al., 2009). One remains concerned at the low physics content of some of these parameterizations. Nevertheless, the concern that the IPCC sea level projections may be biased low has been reinforced by a comparison of observed and projected sea level rise from 1990 to the present. For this period, observed sea level has been rising at the very upper end of the IPCC TAR projections (Holgate and Woodworth, 2004; Rahmstorf et al., 2007), indicating once more that one or more of the model contributions to sea level rise may be underestimated.

Future IPCC assessments are likely to pay greater attention to regional changes in MSL, as opposed to global-average ones, and include in impact studies the role of regional land movements. In addition, they will study in more detail changes in climate extremes (extreme sea

levels leading to coastal flooding in this case) as well as in climate means (MSL in this case). For example, the decimetric twentieth century sea level rise has already doubled the risk of flooding since 1901 at many locations around the UK coastline. If sea level rises faster in the twenty-first century, as suggested by the AR4, there will be greater risk to the coastal environment and infrastructure. In addition, climate-related changes in regional wind fields will result in changes in storm surge frequency and magnitude which will modify the changes in risk due to MSL rise alone (Woodworth et al., 2007; Lowe et al., 2010).

### Need for ongoing monitoring of sea level

Descriptions of global and national sea level networks and their data sets can be found at the web sites of the PSMSL and the Global Sea Level Observing System (GLOSS, [www.gloss-sealevel.org](http://www.gloss-sealevel.org)), while methods for monitoring sea level are explained in the PSMSL training web pages. Real-time data provision, in addition to the delayed-mode data needed for scientific research, is increasingly encouraged for two reasons: the data are then available to a wide range of new users in “operational oceanography” including coastal protection; and faults can be identified faster, leading to better delayed mode data sets in the long term. Some sea level stations are now “multi-hazard” sites, with sensors specifically designed for the high rate recording needed for tsunami monitoring. It is clear that the world needs a coordinated and complete sea level monitoring network at global, regional, and local scales, including information both from in situ sources and from a range of space-based instrumentation (notably altimetry and space gravity, Wilson et al., 2010).

## RED SEA AND GULF OF AQABA

Yonathan Shaked<sup>1</sup>, Amatzia Genin<sup>1,2</sup>

<sup>1</sup>The Interuniversity Institute of Marine Sciences, Eilat, Israel

<sup>2</sup>The Hebrew University of Jerusalem, Jerusalem, Israel

### Definition

The Red Sea is a narrow elongated water body extending some 2,000 km SE–NW, between latitudes 16°N and 28°N, from the Gulf of Aden through which it connects from the Gulf of Aden (through which it connects to the Indian Ocean) to the Gulf of Aqaba (Figure 1). It is flanked by east Africa (Egypt, Sudan, Eritrea, and Djibuti) to the west and Arabia (Saudi Arabia and Yemen) to the east. The Red Sea hosts spectacular coral reefs that pertain to the Indo-Pacific domain. Its northern tributaries, the Gulfs of Suez and Aqaba (reaching latitude 29.5°N) are home to some of the northernmost coral reefs in the world.

**Red Sea And Gulf Of Aqaba, Figure 1** Satellite image of the Red Sea and its northern tributaries, the Gulfs of Suez and Aqaba.

## Red Sea coral reefs – geology and ecology

### Setting

An incipient oceanic basin separating the African Plate from the Arabian Plate, the Red Sea was born as an extensional basin during the late Oligocene – early Miocene, with actual sea floor formation occurring since about 5 million years ago at its southern part. The Red Sea is connected to the Indian Ocean by way of the shallow and narrow sill of Bab-el-Mandeb (137 m deep and 29 km wide) and the Gulf of Aden.

From its southern end at Bab-el-Mandeb, the Red Sea extends nearly 2,000 km until it diverges into two smaller gulfs, the Gulf of Suez and the Gulf of Aqaba. This junction connects the mostly extensional Red Sea with the abandoned rift of the Gulf of Suez and the mostly left-lateral Dead Sea transform of which the Gulf of Aqaba is an active part. Rifting processes resulted in block tilting and an asymmetrical bathymetry across the Red Sea. The Egyptian–Sudanese (western) margin is steep with a narrow shelf and deep pull-apart basins floored by oceanic crust, whereas the Arabian (eastern) margin is less steep and floored by attenuated continental crust. The Red Sea proper is up to 350 km wide and has a maximum depth of 2,800 m, but its average depth is only ~450 m, since around 40% of the Red Sea is shallower than 100 m. The Gulf of Suez is about 320 km long and 70 km wide, with a maximum depth of less than 100 m, while the Gulf of Aqaba is 180 km long and up to 25 km wide with an average depth of 900 m and a maximum depth of nearly 1,850 m.

The margins of the sea on land form elevated shoulders reaching up to 3,000–4,000 m, a few tens of kilometers away from the shore. The coasts are generally narrow, with little or no coastal plain, and sandy beaches are found only in the vicinity of creek valley outlets. The Red Sea is surrounded by deserts and evaporation greatly exceeds precipitation. Freshwater input from the continent is limited to occasional flash floods.

### Reefs – morphology, distribution, and description

Warm temperatures and little runoff support reef growth, and active tectonics create steep margins that are often coral-covered to a depth of several dozen meters. On shallower slopes and wider margins, shallow reef shoals and a few coral islands develop.

Fringing reefs are the most common form of coral terraces along the coasts of the Red Sea (Head, 1987), but some patch reefs and coral islands also occur, especially off the Sudanese coast and the southern parts of both the western and eastern coasts. In general, reefs are better developed along the northern part of the Red Sea down to about latitude 18–20°N (Behairy et al., 1992), although coral growth rates were found to be higher in the south, decreasing northwards (Schuhmacher et al., 1995). To the south, sandy beaches become increasingly abundant and mangroves occupy parts of the coasts. At the southern parts of the Red Sea, reefs of coralline algae are also found

(Behairy et al., 1992). Fringing reefs on the northern parts of the Red Sea are generally narrow, being limited by the steep coastal margins, and form deep “walls”. To the south, the coastal plain is wider and the margins are less steep, allowing the development of wider lagoons and reefs further from shore. Patch reefs somewhat removed from the shores may form chains resembling barrier reefs. Along the coast from Al-Wadj south to Jeddah (eastern shore), a long chain of patch reefs was called the “Little Barrier Reef” by Sheppard (1985). Further south, groups of coral-supporting islands are found on both sides of the sea – the Dahlak and Farasan archipelagoes off the coast of Eritrea and Saudi Arabia, respectively. Some of the reefs growing on wide shallow carbonate platforms in the central and southern parts of the Red Sea have a circular shape enclosing a lagoon, thus resembling Pacific atolls. The best studied of these is perhaps Sanganeb Atoll, off Port Sudan (Schuhmacher and Mergner, 1985; Mergner and Schuhmacher, 1985; Reinicke et al., 2003). Many of the modern coral reefs along the Red Sea grow over fossil Pleistocene reefs.

Fringing coral reefs are also the overwhelmingly dominant form along the shores of the Gulfs of Suez and Aqaba, where the former are smaller and less developed than the latter. The difference may be due to the low winter temperatures at the shallow Gulf of Suez. At greater depths, down to at least 65–70 m, coral carpets covering marginal slopes are abundant. Growth of these deep reefs is facilitated by the clarity of the water that allows light penetration to a depth of ~100 m.

### Geological history of coral reefs at the Red Sea

Coral reefs seem to have been intermittently present along the shores of the Red Sea since Miocene times, persisting during periods in which good connection with the open ocean was maintained. Connection of the Red Sea with the Mediterranean finally ceased during the Pliocene, and from that period Indo-Pacific flora and fauna were introduced (Braithwaite, 1987). During glacial periods, the combination of low temperatures, high evaporation, and restricted water passage over the shallow sill at Bab-el-Mandeb due to low sea level possibly prevented the development of coral reefs. Conditions at the northern Red Sea and Gulf of Aqaba during the last glacial maximum are estimated at 4–5°C lower than present-day temperatures and salinity in the range of 50–53‰ (Arz et al., 2003; Siddall et al., 2003; Almogi-Labin et al., 2008).

Fossil Pleistocene coral reefs are found along the Red Sea coasts on both sides, off of Sudan and Saudi Arabia. These reach an elevation of at least 16 m above current sea level. Raised fossil coral reefs are also present at the Gulfs of Suez and Aqaba, with terraces at the Gulf of Aqaba, dating as far back as 300 ka, reaching some 35 m above sea level (Figures 2, 3; Gvirtzman et al., 1992). Fossil sequences of 3–4 reef complexes are found along the southern coast of Sinai and at the northeastern end of the Gulf of Aqaba, just south of the city Aqaba (Friedman, 1968; Gvirtzman et al., 1992; Al-Rifaiy and Cherif, 1988). The elevated Pleistocene sequences seem to represent Pleistocene highstands, reaching their present elevation as a result of uplifting tectonic movements along

**Red Sea And Gulf Of Aqaba, Figure 2** Uplifted fossil Pleistocene coral reefs covered by beach rock some 20 m above the sea. South of Aqaba, on the northeastern side of the Gulf of Aqaba. (Photo courtesy by Y. Shaked.)

**Red Sea And Gulf Of Aqaba, Figure 3** Fossil corals comprising uplifted Pleistocene reefs south of Aqaba. (Photo courtesy by Y. Shaked.)

those margins of the Gulf. On Tiran island at the entrance to the Gulf of Aqaba, where uplifting tectonics have particularly high rates, marine coastal terraces are found up to 500 m above the present-day sea level. Fossilized late Pleistocene fringing reefs are recognized to an elevation of 60 m above sea level, where an age of 146 ka was determined from a terrace at 40 m (Goldberg and Beyth, 1991).

Submerged terraces, such as those found at ~120 and 65–70 m depth along the northwestern end of the Gulf of Aqaba (Makovsky et al., 2008), likely represent lower sea level stand-stills. A reliable age control of these submerged features is not yet available. Since conditions at the Red Sea and its subsidiary gulfs were not favorable to reef formation during glacial periods, it seems that most modern reefs were established during the Holocene (Braithwaite, 1987). A coral from a fossil reef retrieved from 11 m below sea level yielded an age of 7,000 years (Shaked et al., 2004). Slightly exposed reefs along both margins of the Gulf of Aqaba indicate a sustained (ca. 7–4 ka) Holocene sea level highstand, ~1 m above present sea level. During this interval Holocene fringing reefs developed morphological reef flats that are now found at or just above the high-tide level, commonly partly eroded and covered with beach rock (Shaked et al., 2004, 2005). The modern reefs are found further offshore and are limited by the present sea level.

#### Present conditions

The Red Sea's deep, elongated morphology coupled with its location within a hyper arid region create a distinct anti-estuarine circulation at Bab-el-Mandeb, where relatively warm water (25.5–30°C) with normal salinity (36.5%) enters the Red Sea from the Gulf of Aden, forming the

surface water layer that cools and evaporates along the route northward. The Red Sea bottom water (21.7°C, 40.6%) is formed mostly in the Gulf of Aqaba (Plähn et al., 2002), flowing into the Red Sea over the shallow (250 m) and narrow (16 km) sill in the Straits of Tiran.

The presence of a shallow sill at Bab-el-Mandeb greatly affects the extent and diversity of the coral reefs in the Red Sea, especially those at higher latitudes in the Gulfs of Aqaba and Suez. Unlike “normal” open oceans, where the deep and intermediate water is cold, the shallow sill at Bab-el-Mandeb effectively separates the deep waters in the semi-enclosed Red Sea from those of the Indian Ocean. For example, the water at 1,500 m depth in the Gulf of Aden (the water body connecting the Red Sea to the Indian Ocean) is <10°C, whereas the deep waters at this and greater depths in the Red Sea is always warmer than 20°C. This characteristic determines the lowest temperature the shallow water can be cooled down to during winter. The ensuing year-round occurrence of warm waters allows coral reefs to flourish throughout the Red Sea, even at the northernmost end of the Gulf of Aqaba.

On the other hand, the occurrence of warm water at depth substantially weakens vertical stratification. For example, below ~300 m, the vertical gradient in temperature in the Gulf of Aqaba is ~0.09°C/100 m, compared with more than an order of magnitude steeper gradient in “normal” oceans at similar latitudes (e.g., 1.07°C/100 m south of Bermuda, 1.67°C/100 m at the Central North Pacific). The weak stratification in the Gulf of Aqaba, together with low air temperature during winter, drives an extraordinarily deep vertical mixing, exceeding 600 m depth in cold winters. The most striking phenomenon driven by this mixing is the recurrence of immense spring blooms of benthic algae that cover wide sections

of the local reefs, sometimes causing substantial coral death (Genin et al., 1995). This “intermediate” disturbance, occurring once every 5–20 years, may be one of the processes responsible for the high coral diversity in the Gulf (Connell, 1978). Note, however, that the occurrence of deep mixing is limited to the Gulf of Aqaba, at the northern end of the Red Sea. Air temperature at lower latitudes, south of the Straits of Tiran, is too high even in winters to induce deep mixing (Paldor and Anati, 1979; Reiss and Hottinger, 1984).

### Modern fauna

While its connection with the Indian Ocean places the biogeographic origin of Red Sea fauna and flora within the Indo-Pacific domain, its setting and geological history make for unique conditions that have direct bearing on the development of reefs along the coasts of this elongated narrow sea. The reefs are dominated by stony, hermatypic corals, consisting of a diverse mixture of branching, foliose, and massive species. Most abundant are corals belonging to the genera *Acropora*, *Stylophora*, *Montipora*, *Pocillopora*, *Porites*, *Platygyra*, *Pavona*, *Echinopora*, and *Favia* (Loya and Slobodkin, 1971). The hydrozoan *Millepora* is very abundant in the shallow, sub-tidal zone. Soft corals are also abundant throughout the Red Sea, dominated by *Sinularia*, *Sarcophyton*, *Lobophyton*, and Xeniids, with magnificent thickets of nephtheids (mostly *Dendronephthya*) found on elevated substrates and vertical walls exposed to strong currents (Benayahu and Loya, 1977). Due to the clear water in the northern Red Sea, zooxanthellate corals reach at least 145 m in depth (Fricke et al., 1987).

The number of coral species found in the Red Sea is approximately 190, belonging to 70 genera (Head, 1987). While the total number of species is generally higher in other tropical Indo-Pacific reefs (e.g., ~360 species in the Great Barrier Reef, Veron, 1986), the local, within-habitat diversity in the Red Sea is exceptionally high, even higher than in the Great Barrier Reef of Australia (Loya, 1972).

The fishes in Red Sea coral reefs, like the corals themselves, share an Indo-Pacific origin. Especially abundant and diverse are the lush guild of site-attached and mobile zooplanktivorous species (Figure 4), including many Damselfishes (Pomacentridae) and the most conspicuous schools of Reef Anthias, and numerous benthic feeding fishes, including Surgeonfishes (Acanthuridae), Parrotfishes (Scaridae), Wrasses (Labridae), Groupers (Serranidae), Butterflyfishes (Chaetodontidae), Triggerfishes (Balistidae), Blennies, and Gobies. Of the 462 reef-associated species that inhabit the Arabian Sea, 69% have crossed successfully into the Red Sea; of these, 55% have crossed into the Gulf of Aqaba. Present-day differences in the species richness of reef-associated species among the Arabian Sea, Red Sea, and Gulf of Aqaba appear to be the product of external, non-selective constraints on colonization (Kiflawi et al., 2006).

The Red Sea coral reefs are among the most studied reefs in the world. Detailed accounts of their structure and biological composition can be found in numerous publications. Some of the useful references include Loya (1972), Loya and Slobodkin (1971), Mergner (1971), Scheer (1971), Fishelson (1971), Benayahu and Loya (1977), and Edwards and Head (1987).

## REEF BALLS

Jason Krumholz<sup>1</sup>, Todd R. Barber<sup>2</sup>

<sup>1</sup>University of Rhode Island, Narragansett, RI, USA

<sup>2</sup>The Reef Ball Foundation, Atlanta, GA, USA

### Definition

**Artificial Reef:** Any manmade structure deposited or attached to the seafloor whether intentional or unintentional, which provides, or attempts to provide a substitute for some of the ecological services provided by natural reefs (e.g., shipwrecks, oil rigs, dumped construction debris, designed/purpose built modules).

**Designed Artificial Reef:** Any manmade structure purposely built and deployed with the intent of serving as an artificial reef (rather than repurposed).

**Breakwater:** A shallow submerged structure positioned in a nearshore high energy environment which absorbs some of the incoming wave energy, reducing the impact on the beach.

**Mitigation:** Human activity intended to compensate for damage done to an ecosystem by a natural or anthropogenic impact (e.g., hurricane, ship grounding, dredging, etc. . .).

**Anthropogenic:** Caused by human activity.

Reef Balls™ are hollow concrete hemispherical designed artificial reef modules built by The Reef Ball Foundation and its licensees, ranging in size from about 13kg (30lbs) to over 4 metric tons (8800 lbs) (<http://www.reefball.org/technicalspecs.htm>). While the term “Reef Ball” is often used incorrectly to describe any of a number of roughly hemispherical artificial reef designs, true Reef Balls possess a number of unique adaptations for a wide range of designed artificial reef applications (Figure 1). Reef Balls utilize a pH balanced microsilicate based concrete

mixture, which is textured to promote natural settlement for hard and soft corals (see also *Corals: Environmental Controls on Growth*). They may also be fit with adapters for coral transplant and rescue operations (Quinn et al., 1999; Bowden-Kerby, 2003), or be anchored for use as a breakwater (e.g., Harris, 2003) (see also *Waves and Wave-Driven Currents*). The shape of a Reef Ball makes it extremely stable, and able to withstand strong hurricane waves when properly engineered and deployed (Harris, 2003; Armonio, 2004). Exclusion of metal components gives Reef Balls an expected lifespan of 500+ years in seawater (ASTM, 2008), an important consideration in the rehabilitation of coral reefs, which are very slow growing (see also *Reef Restoration*).

Artificial reefs have been increasingly utilized for habitat rehabilitation and mitigation of anthropogenic impact (e.g., Pratt, 1994; Pickering et al., 1998, see Chapters *Reef Restoration*, *Reefs at Risk: Map-Based Analyses of Threats to Coral Reefs*) (Figure 2), but the degree to which artificial reefs can accomplish these goals is still a topic of scientific scrutiny (e.g., Osenberg et al., 2002; Baine, 2001; Powers et al., 2003). However research shows that artificial reef units with higher levels of habitat complexity and void space are capable of supporting more biomass and diversity of fish per square meter of restored area (Charbonnel et al., 2002; Sherman et al., 2002), and that artificial reefs which better approximate natural habitat can more closely approximate the natural fish and invertebrate communities (Perkol-Finkel et al., 2006) (Figure 3). This research tends to support the use of designed artificial reef units (such as Reef Balls) over other traditional artificial reef building materials (typically materials of opportunity, such as concrete rubble, ash blocks, tires, or construction debris which less closely replicate natural habitat). It is important to note, however, that no

**Reef Balls, Figure 1** Reef Balls staged on a boat awaiting deployment (left). Note the small circular adaptor holes on the tops and sides of the balls, used for transplant of coral fragments. form of restoration or mitigation can equal the ecosystem services provided by the natural habitat, so the best form of restoration is always conservation (e.g., Young, 2000) (see also *Conservation and Marine Protected Areas*).

The successful use of Reef Balls has been scientifically documented for project goals ranging from breakwaters

and erosional stability (Harris, 2003), to oyster culture (Wall et al., 2005) and mangrove restoration (Krumholz and Jadot, 2009). However, despite extensive use in fisheries augmentation coral rescue, and mitigation (e.g., Edwards and Gomez, 2007; Bowden-Kerby, 2003), the ability of designed artificial reefs to succeed in these roles

**Reef Balls, Figure 2** Newly deployed Reef Balls in a breakwater formation in Grand Cayman, BWI. Submerged Reef Ball breakwaters offer a softer more porous approach, providing many of the benefits of traditional beach hardening techniques while also providing habitat for fish and invertebrates. has yet to be systematically evaluated (e.g., Osenberg et al., 2002; Baine, 2001; Powers et al., 2003).

Since its inception in 1993, the Reef Ball Foundation has implemented or overseen the placement of over 500,000 Reef Balls in about 4000 projects in 60+ countries. The Foundation's mission is to help restore the world's ocean ecosystems through the development and use of aesthetically pleasing, ecologically sound, and economically designed artificial reefs, emphasizing on-going research, public education, community involvement, and reefs that promote and support natural species diversity and population density.

## REEF CLASSIFICATION BY FAIRBRIDGE (1950)

---

Charles W. Finkl

Florida Atlantic University, Boca Raton, FL, USA

## Introduction

Coral reefs have been the subject of scientific interest for the last century and a half, with Darwin's (1842) descriptions of the basic reef forms (i.e., fringing, barrier, and atoll reefs) still in common use today. In the Australian Indo-Pacific region, originally Fairbridge (1950) mainly focused on the Great Barrier Reef (GBR) in broad outline but later elaborated and extended his system to more comprehensively include the whole of the Australian region (Fairbridge, 1967), covering in more detail reefs on the west coast continental platform along western and north-western Western Australia as well as those reefs occurring along the northern margins of the continent offshore the Northern Territory and northern Queensland in the Arafura Sea and Torres Strait.

The Fairbridge classification of Holocene and Pleistocene reefs is comprehensive in that it covers the salient morphological reef forms on the relatively stable epicontinental Australian shelf environment. He recognized fringing, barrier, atoll, and platform reefs along with five varieties of coral island. This basic classification was initially modified and expanded by Maxwell (1968), and then subsequently more comprehensively described by Hopley (1982) and Hopley et al. (2007). Fairbridge's first description in the *Journal of Geology* (Volume 58, pp. 330–401), about 70 pages long, was based in part on Rhodes' exposure to the photo-interpretation of coral reefs during World War II. This fortuitous occurrence is noted by Hopley et al. (2007), who state that:

"...Fairbridge was possibly the first person with a geoscientific background to view the variety of reefs, the planimetric details of which had not been previously seen. Such a view gives new insight into the role of waves and currents in the formation of reefs whilst the appreciation of the range of morphology led for the first time to an evolutionary type of classification of modern reefs." (p. 12).

Using his geoscientific background based on interpretation of reef borings and structural and geomorphological features, Fairbridge posited that the shape of coral reefs is generally controlled by wind, waves, and currents but complex forms could also be influenced by antecedent bottom topography, sedimentation, and eustatic fluctuations.

As far as reef types are concerned, almost all of the “standard” forms are known to occur in the region, based mostly on observations of the GBR which extends over 19,300 km along the Queensland coast (Fairbridge, 1950). Most common in the region are irregularly shaped reefs, which do not fit into any standard category – the platform or patch reefs, which are also alternatively referred to as bank or hummock reefs (Fairbridge, 1950, page 332). Atolls are rare on the Australian shelf but were reported to occur sporadically off the northwestern coast and on the Queensland shelf. At this time, fringing reefs were recognized as being common in the north but it is now widely recognized that Australia’s largest fringing reef occurs on the West Australian shelf (Collins et al., 2003). Ningaloo Reef, located about 1,200 km north of Perth, is 300 km long and it is also the world’s only large reef located so close to a landmass. At its point closest to the continent, the reef is just 100 m from shore; at its farthest point, it is less than 7 km away.

### Fringing reefs

As summarized by Kennedy and Woodroffe (2002), it is now known that fringing reefs grow along the shore under a great variety of conditions that are imposed by climate, vegetation, soils and sediments, and rock materials of the adjacent land mass. Several decades ago, Fairbridge (1950) noted that fringing reefs of the Australian mainland are among the poorest of reef types due to rigorous conditions near the shore, excessive sedimentation, dilution of seawater by fresh water, and acidic waters from the land. More vigorous fringing reefs often encircle offshore continental islands where growth conditions are more favorable. Smithers et al. (2006) have additionally shown that fringing reefs of the GBR have experienced several critical growth phases since the mid-Holocene. They report that the apparent synchronicity of these growth-and-quiescent phases over wide geographical areas are related to the involvement of broad-scale influences such as climate and sea-level change. But, in general, as observed by Fairbridge long ago, (episodic) living coral growth is confined to the outer reef edge, where there may be a *Lithothamnion* ridge, whereas behind it there is a dead reef, about a meter below low-water springs, lightly sand covered and marked by the radial pattern of seaweed. The reef flats often contain coral shingle, and living coral is absent except in tide pools. Landward-most parts of some fringing reefs are characterized by mud-covered reef that is in the process of colonization by mangrove. Morphological zonation often follows an outer to inner reef pattern of reef edge, trickle zone, sand flat mangrove. Good examples occur in the Whitsunday Group, the

Lizard Islands, and the Murray Islands off the Queensland coast (Fairbridge, 1967). The geographic distribution of coral reef types in the Australian region is shown in Figure 10 of Fairbridge (1950). Figure 17.4 of Fairbridge (1967) details locations of reef types of the GBR, Coral Sea, and southeastern Papua New Guinea. Figure 17.8 in the same publication shows shelf regions around the Australian island continent as well as some other prominent geographic features relevant to the study of coral reefs.

### Barrier reefs

Fairbridge (1950) states that the only barrier reefs in Australia are the outermost belt of the Queensland reefs. Barrier reefs are always strongly asymmetric in planview and cross-section, being steep on the ocean side and grading towards the land with a sediment wedge dotted by small reef patches, pinnacles, and coral heads (Fairbridge, 1967). Incipient barriers may include small fringing reefs around islands within the main lagoon, such as Lizard Island. Discontinuous reefs near the edge of the Sahul Shelf may be genetically linked to the barrier type, but from a morphological point of view they are only patch or platform reefs, as described by Fairbridge and Teichert (1948). Fairbridge (1967) states that the world’s best example of a barrier reef system occurs along the Queensland coast from the Gulf of Papua to the Tropic of Capricorn, a distance of 1,900 km. In his 1950 classification, Fairbridge recognized two main types of outer-barrier reefs: ribbon reefs and platform reefs.

The **ribbon-reef zone**, containing ribbon-shaped reefs (the ‘linear reefs’ of Jukes, 1847), occurs as a festoon along the outer edge of the continental shelf. Here, the ribbon reef ranges between 300 and 450 m in width and 3–25 km in length. The ribbons are separated from one another by narrow passages generally about a kilometer wide. Typical of this type and extensively studied is the Yonge Reef east of Lizard Island. This ribbon reef consists of an outer parapet-like fringe of living corals that are furrowed by wedge-shaped channels or chutes. Inside the margin, there is a shallow zone or outer moat, which is occupied by irregular patches of living coral, negroheads, and boulders that are heavily washed by surf. The reef crest rises gently from here, often including a *Lithothamnion* rim of calcareous algae about 1–2 m above low-water springs. The reef material consists of debris containing broken corals, boulders, shells, and sand, cemented together and often encrusted by *Lithothamnion*. The so-called “trickle zone” or “radial zone” occurs on wider parts of the reef where sediment debris and algae form a definite pattern normal to the reef edge. A shallow “inner moat” occurs inside the rim, partly filled with clumps of living coral, boulders, and sediment. From here, the floor deepens gradually and tends to be covered with white coral sand of the “sanded zone.” Farther out in deeper waters of the lagoon, only a few larger coral heads reach the surface. This typical morphological sequence is also reported by Agassiz (1898).

The **barrier platform reefs** occur south of about 16° latitude, providing a distinct change in reef morphology from ribbons in the north to irregular-shaped patch or platform reefs. Fairbridge (1950) reports that they occur about 5 km or more from the 200-m isobath and seem to be separated by deep channels. Fairbridge does not elaborate on the morphological or ecological zones because he reports that they are less clear and not well known here.

### Atoll reefs

Fairbridge (1950) uses the term “atoll” in an exclusively morphological sense in reference to ring-shaped ribbon reefs that enclose a central lagoon. He reports that there is no marked difference in appearance between an “annular reef” rising from an oceanic cone or platform and one rising from the continental shelf. The most morphologically perfect atolls occur on the Northwest Shelf in the Indian Ocean and on the Sahul Shelf. Examples of the former include Mermaid, Clerke, and Imperieuse reefs. Scott Reef on the Sahul Shelf is a *paired atoll* containing one annular reef in the north and a horseshoe reef in the south. Seringapatam Reef, on the other hand, is a *perfectly enclosed reef* with a central lagoon that is approximately 36 m deep. Fairbridge (1950) reports that in section the reef is similar in morphology to the outer-barrier ribbon reefs of Queensland, except that it is about 300–1,200 m wide. Boulders occur along the reef crest and small shingle forms “hammerhead” spits. The wide reef flat accommodates the radial zone that is produced by algae, boulders, and sediment. A “sanded zone” breaks up into coral patches towards the lagoon.

Fairbridge classifies the Houtman Abrolhos group off northwestern Western Australia in the Indian Ocean (29° S.) as “shelf atolls” (Fairbridge, 1950, p. 342). The four groups from south to north and in decreasing order of size are the Pelsart, Easter, Wallaby, and Northern groups. These complex reefs, irregular and discontinuous, are essentially annular. Classification of these reefs is complicated by the fact that in the Pelsart group they have cores of eroded (truncated) Pleistocene reef material. Pleistocene coral limestone is also marginally exposed on the islands but is overlain by and replaced in the interior by a lagoonal limestone (a white calcareous mudstone). According to Fairbridge (1950), other groups in the Abrolhos differ morphologically from the Pelsart but appear to have gone through the same evolutionary sequence. In many cases, however, it is difficult to ascertain for classification purposes which parts of these reefs are contemporary and which are Pleistocene in age.

*Shelf atolls*, which occur on the Queensland Shelf near Cape Melville and on the Sahul and Rowley Shelves off northwestern Australia, may have volcanic foundations, be set on salt dome prominences, or simply have grown up from Pleistocene platform reefs (Fairbridge, 1967). On the surface, shelf atolls are morphologically similar to mid-Pacific atolls, but they definitely rise from the shelf instead of being founded at 1,200–1,500 m depths.

*Compound atolls* occur where continental crustal segments have slowly subsided, allowing barrier and platform reefs to grow upwards in the same manner as atolls. The Houtman Abrolhos Islands on the Western Australian shelf in the Indian Ocean contain parts of old coral reefs that are exposed, deeply weathered, and penetrated by deep holes (former karst pipes and solution holes).

*Oceanic Atolls* are the so-called mid-Pacific type, which rise from isolated volcanic cones in the deep ocean basins (e.g., from seamounts or guyots) with 1,200–1,500 m of accumulated reef growth. Fairbridge (1967) reports that these are quite rare in the Australian region but some are known in the Coral Sea and in the northern part of the Tasman Sea (Elizabeth, Middleton Atolls).

### Patch or platform reefs

The most numerous of the coral reefs around Australia and quite distinct from the fringing reefs, barrier types, and atolls, these reefs are without islands and are largely awash except at low tide. Fairbridge (1950, 1967) applied the term “patch reef” (also referred to as shelf, bank, table, or hummock reef) to the smaller ones (<2 km long) and “platform reef” to the larger ones (>2 km long). He emphasized that the adjective “platform” only means that the reef has a broad, flat, tabular morphology and that the term does not have any genetic significance because it does not imply growth from an antecedent platform. Most of these reefs occur in the GBR lagoon, in the Torres Straits almost blocking the channel between Australia and Papua New Guinea, and scattered along the northern edge of the Sahul Shelf. Deeper water reefs in about 30 m water depth on the interior of the Sahul Shelf off the rocky northwest Kimberly coast, such as the West Holothuria reefs and Long Reef, rise from submerged banks or terraces and are classified as platform reefs. Numerous others lie offshore from northwestern Australia in the Dampier Archipelago, and intermittently down the coast to the Northwest Cape where small patches occur in association with the Western Australian “sandstone reefs” and the Abrolhos atoll groups.

Because these reefs formed without islands, they lack features such as sand cays, shingle banks, and raised reef remnants, and their surface is simplified. From the reef crest, for example, just behind the breaker line, there is a broad, radially striated “trickle zone” of sediment debris and algae. Within the trickle zone there may be well-defined sand flats consisting of bare expanses of coral sand and small boulders that are interrupted by shallow pools fringed or carpeted by growing coral, *Mollusca*, *Halimeda*, and *Zostera*.

### Coral reefs with islands

Australian reefs contain islands comprised of calcareous fragmental coral, molluscan, algal, or foraminiferal sand or coral shingle. Classification of coral reefs with islands is somewhat complicated, as there were other attempts prior to Fairbridge’s effort. Steers (1929), for example,

classified islands with mainland bedrock as “continental” or “high” islands, whereas Hedley and Taylor (1908) referred to them as “hilly timbered islands”. Spender (1930) classified true coral islands into five types: islandless reefs with scattered debris only, (2) reefs with a sand cay but no shingle ramparts, (3) reefs with sand cay and ramparts but with no vegetation on the latter, (4) reefs with sand cay and ramparts with vegetation, and (5) reefs with all the features of class 4 together with a mangrove swamp on the reef flat. Steers (1937) later adopted Captain Cook’s term “low wooded island” for Spender’s Class 5, subdividing those with mainly sand and beach rock and those prevalently with shingle. With these classifications in mind and based on his own field experience, Fairbridge presented a revised classification of coral island types. Type 1 (Sand Cay, Unvegetated) refers to those islands that are commonly unstable and which migrate seasonally. They are found in all areas except on fringing reefs. Type 2 (Sand Cay, Vegetated) refers to islands that are moderately stabilized with beach rock. They are widely distributed but generally lacking in the outer reefs. Type 3 (Shingle Cay, with or without Vegetation) identifies moderately stabilized islands that are widely distributed but found mostly on smaller, more exposed reefs. Type 4 (Sand Cay with Shingle Ramparts) are unvegetated to vegetated islands, including mangrove swamp. Although restricted to smaller reef platforms in protected areas of the northern GBR lagoon, this category overlaps Type 5, as small pavements or promenades (benches) of older emerged reef-core material are commonly associated with the rampart system (Steers, 1937). Type 5 (Island with Exposed Platform of Older, Emerged Coral-Reef Material) takes in reef islands with or without a fringe of recent sand or shingle beach ridges or ramparts. The platform is vegetated and stable. In the 1967 book chapter (*Landform Studies from Australia and New Guinea* edited by J.N. Jennings and J.A. Mabbutt), Fairbridge more elegantly classifies reef islands into five categories: (1) Simple Sand Cays, (2) Vegetated Sand Cays, (3) Shingle Cays, (4) Sand Cays with Shingle Ramparts, and (5) Emerged Reef Islands.

## Conclusions

Coral reefs of the Australian shelf region are classified by Fairbridge into four principal types based on morphology: fringing, barrier, atoll, and platform. These terms have no genetic implication. Coral reef islands are classified in terms of five basic types: unvegetated sand cay; stable, vegetated sand cay; shingle cay; sand cay with shingle ridges or ramparts on the reef platform; coral islands with partly eroded core of older emergent coral limestone. Reef morphology is controlled by winds, waves, and currents. The stages of reef evolution range from initial patch reefs and crescentic or horseshoe patch reefs. Following these stages the larger (semi-atoll) and smaller (horseshoe-shaped reef) types develop differently, the former margining into a complete atoll which is followed by an infilled platform reef. The end stage of horseshoe-shaped

reefs is a small oval reef platform. Reef platform shape is also influenced by antecedent geomorphological and structural features. Coral islands on the Australian shelves form by accumulation of sand or coral shingle under wave action to form cays or by eustatic drop in sea level to expose older coral reefs. The Fairbridge (1950, 1967) classification of coral reefs on the Australian shelves supported, at that time, improved perspectives on the types of reefs and their geographic distributions in the eastern Indian Ocean, Coral Sea, Gulf of Papua, Torres Strait, Arafura Sea, and the Timor Sea. The Fairbridge classification for Australian coral reefs provided a stepping stone to further refinements and increased understanding of reef types, their spatial distribution patterns, and evolutionary modes.

## REEF CLASSIFICATION BY HOPLEY (1982)

---

David Hopley  
 James Cook University, Townsville, QLD, Australia

### Definition

Classification is an analytical procedure denoting the typology of coral reefs based on factors such as morphology, age, size etc. The classification described here is derived from the evolution of continental shelf reefs on the Great Barrier Reef during the Holocene.

### Introduction

By the early 1980s, reef classifications derived from the morphologies of the Great Barrier Reef (GBR) reefs were available. Notably, these were

1. The relatively simple model of Fairbridge, which showed reefs developing from initial patches under the influence of prevailing winds and waves into larger platforms (see Entry *Reef Classification by Fairbridge (1950)*, this volume) and
2. That of Maxwell (1968), which had the advantage of aerial photography of a large proportion of the GBR. Again, small reef patches are extended by prevailing wind and waves but the larger platforms are not the end result, which, instead, is a complex form termed

as “resorbed” reef formed from the degeneration of a previous reefal mass.

Subsequent to these two classifications, there became available during the 1960s and 1970s much greater understanding of reefal processes and environments. In particular was the influence of the 1974 paper by Purdy which examined the karst features formed on reefs during long glacial periods of exposure and which showed the influence of these features during the Holocene transgression when rising sea levels recolonized the older Pleistocene foundations. A saucer shape with marginal rims around a central depression (the lagoon) was attributed to karst processes by Purdy and others. Isolated coral pinnacles evolved over tropical tower karst, spur, and groove as an expression of *lapiés* and blue holes as drowned dolines. The drowned karst theory played an important role in reef research during the 1970s and 1980s as the depth to the Pleistocene was determined by drilling and seismic investigation.

Also prominent at this time were new ideas on sea-level change, most prominently the influences of hydroisostatic shelf warping (e.g., Walcott, 1972; Chappell, 1974). The GBR was a particular focus of research, with various models of shelf warping published in the early 1980s (Chappell et al., 1982; Hopley, 1983). With modern sea level achieved about 6,500 years ago, higher sea levels (ca. 1 m) were found along much of the inner shelf due to hydroisostasy, while, where the shelf was wide, outer shelf submergence occurred (for review of latest mid-Holocene sea levels on the GBR, see Hopley et al., 2007).

Rates of reef growth from both dated drill cores (Davies, 1983; Davies and Hopley, 1983) and alkalinity anomaly measurements (Kinsey, 1985) also provided data which could be fed into evolutionary reef classification. By the late 1970s, aerial photography at a scale of about 1:60,000, was available for the whole reef, intended to aid in the management of the Great Barrier Reef Marine Park (GBRMP), set up in 1975. It was from this very large dataset and the greater understanding of reef development that the Hopley (1982) reef classification scheme developed. Subsequent to the formulation of the classification, a gazetteer was compiled for the Great Barrier Reef Marine Park Authority (GBRMPA), upon which analysis of the GBRMP was subsequently undertaken (Hopley et al., 1989). This was additional to the first comprehensive mapping of the GBR based on LANDSAT satellite imagery of the 1970s.

### Background to the evolutionary classification

The basic presumption of the 1982 Hopley reef classification is that during the final phases of the Holocene transgression, Pleistocene reefal foundations that had been subaerially exposed for much of the time since the last interglacial were slowly drowned and recolonized by a Holocene veneer. Modal accretion rates were about 7–8 m/1,000 years (Davies and Hopley, 1983), so that where reefs commenced growing from relatively shallow

(<12 m) foundations, a “keep up” mode of growth was possible (see Macintyre and Neumann, this volume). Once reefs reached sea level, vertical growth was converted to lateral growth and sediment movement. Thus, reefs growing from shallower karstified surfaces tend to be more mature in the evolutionary sequence than ones growing from deeper foundations.

This classification is set within the sea-level mode of the GBR, i.e., modern sea level first achieved about 6,500 years ago, possibly a little higher on the inner shelf and a little lower on the outer shelf. The result is for inner shelf reefs to be more mature with low wooded islands which retain evidence of higher sea levels in the form of micro atolls and cemented platforms. On the GBR, the area of youngest reefs is where the Pleistocene foundations are deepest (<20 m) and hydroisostatic subsidence is active (Chappell et al., 1982; Hopley, 1983; Lambeck and Nakada, 1990).

Although the classification published in 1982 was derived from the data and environment of the GBR, it has been tested on other reefs and is applicable to most continental shelf reef systems taking into account Holocene sea-level history, depth to the Pleistocene foundations, and the size of reefs involved as discussed below.

### The 1982 evolutionary reef classification system (Figures 1 and 2) (Hopley, 1982; Hopley et al., 2007)

Evolving from the recolonization of Pleistocene foundations, the classification identifies three phases:

1. *Juvenile* – mainly upward growth and enhancement of the Pleistocene relief
  - (a) Unmodified antecedent platforms
  - (b) Submerged reefs – reefs with some Holocene growth, mainly on the highest parts of the antecedent platform but not reaching modern sea level
  - (c) Irregular reef patches – patchy reef flat development from the highs in the antecedent platform
2. *Mature* – horizontal extension of the modern reef flat
  - (d) Crescentic reefs – coalescence of patch reefs on the most productive windward margins to produce a crescentic shaped reef with open back reef area
  - (e) Lagoonal reefs – extension of the reef flat around the most productive margins of the foundations to enclose or partly enclose one or more lagoons
3. *Senile* – masking of the original Pleistocene relief
  - (f) Planar reefs – infilling of lagoons by internal patch reef growth and sediment transported from windward margins to produce extensive reef flat, eventually with a widespread sediment blanket. Islands can form at this or earlier stages with appropriate area of reef flat and wave transport.

Not all shelf reefs will be included in this classification, the main focus of which was to identify a sequential model of reef development and eventually the rate at which reefs

progress through the system. Other reefs that need a separate classification include fringing reefs (Smithers et al., 2006) and linear barrier or ribbon reefs which, apart from their relationship with sea level, are difficult to place in an evolutionary sequence. However, within the GBR Marine Park, there are 2,877 shelf reefs (Hopley et al., 1989) excluding fringing and ribbon reefs, providing an unmatched dataset for the development of an evolutionary model of reef classification (numbers from the new GBRMPA GIS dataset analyzed in Hopley et al., 2007). For many of these reefs, there is information from drilling, dating, and seismic profiling which, together with estimates of calcification rates, allow calculation of the rate of reef growth and progression, from one morphology to the next in the sequence (see Hopley et al., 2007, Chapter 8).

### Rates of reef growth and evolutionary change

The rates of reef morphological change (Hopley et al., 2007, Chapter 8) are influenced by a number of factors:

1. The depth of the Pleistocene surface is up to 30 m below present reef flat level, the deeper foundations being drowned earlier by a rapidly rising sea level and adopting a “catch up” mode (see Macintyre and Neumann, this volume) while shallower foundations were drowned by a more slowly rising sea level and adopted a “keep up” mode. Radiocarbon dates from the upper 3 m beneath the reef flat have a very strong correlation with depth to the antecedent surface, with shallow foundations producing reef top ages of 6.5–5.5 ka and deeper foundations progressively younger. On small reefs (<1.5 km<sup>2</sup>), reef flats evolved rapidly as reef top patches coalesced into crescentic reefs on windward margins.
2. In reefs where drilling and dating data are sufficient to draft isochrons, smaller reefs (<1.5 km<sup>2</sup>) may evolve directly from reef patches to planar reefs as the patches coalesce over the whole reef platform. On slightly larger platforms, the transformation from patch to crescentic is about 700 years and from crescentic to lagoonal ca. 1,350–1,800 years (Hopley et al., 2007).
3. Progression from lagoonal to planar reef is a more complex process, as lagoonal infilling comes from both internal growth of patch reefs (the most rapid framework construction within the reef, Davies and Hopley, 1983) and sediments derived from the reef rim. There are three sedimentation modes:
  - (a) For the densely covered reef slope 10 kg m<sup>2</sup>/year, which converts to an upward accretion rate of 7 m/ka;
  - (b) For the reef flat, which converts to 3 m/ka, 4 kg m<sup>2</sup>/year. The reef flat, however, has a self-limiting width of 400 m (see Kinsey and Davies, 1979), which means that the area of productive reef flat to lagoonal area is much smaller on larger reefs, which hence have a slower infilling rate.

Reef Classification by Hopley (1982), Figure 1 Evolutionary classification of shelf reefs (Hopley, 1982).

- (c) Productivity of the lagoon is low at  $<2 \text{ kg m}^{-2}/\text{year}$  producing only a  $1.5 \text{ m/ka}$  infilling rate (Kinsey, 1985).

The dataset used by Hopley et al. (2007) included reefs with areas of  $1.9\text{--}18.1 \text{ km}^2$  with representative diameter values of  $1\text{--}5 \text{ km}$ , thus illustrating the much smaller area of reef flat: lagoon for larger reefs. Larger reefs have younger reef top ages, providing a strong negative correlation.

Smallest reefs in the GBR with shallow foundations have progressed from lagoonal to planar stages in  $1,000\text{--}2,000$  years. For larger reefs with deeper foundations, the time required has been  $>5,000$  years. For reefs with more than  $20 \text{ km}$  diameter and with a Pleistocene foundation  $20 \text{ m}$  deep, the suggested time required is  $>10,000$  years. Such reefs may have inherited their morphology from a previous interglacial, and with interglacial

**Reef Classification by Hopley (1982), Figure 2** (a) Reef patches – GBR off Innisfail. (b) Crescentic reef – Viper Reef, GBR. (c) Open lagoonal reef – GBR off Bowen. (d) Infilling closed lagoonal reefs – Heron and Wistari Reefs, GBR. (e) Remnant lagoon – Redbill Reef, GBR. (f) Planar reef – Coconut Island (Poruma), Torres Strait.

periods being about 10,000 years long, there may have been insufficient time for major changes in morphology within the Holocene or any other recent interglacials.

## Conclusions

The analysis of changing morphology of Holocene reefs of the GBR appears to justify the presented evolutionary model of reef classification. Purdy and Gischler (2005) suggested that uplift could accelerate the lagoonal infilling stage and this would appear to be confirmed by the GBR. Planar reefs representing the end stage of the classification are clearly more numerous on the inner shelf (see Hopley et al., 1989) where hydroisostatic uplift has been demonstrated (e.g., Lambeck and Nakada, 1990). However, all stages in the classification exist, indicating the range of controlling conditions on the GBR – reef size, depth to the antecedent surface, and rates of calcification processes. Small variations may occur, for example, through contrasting Holocene sea-level histories, but the influences described are global and the classification is applicable to most shelf-reef systems.

## REEF CLASSIFICATION BY MAXWELL (1968)

---

Peter Flood  
 University of New England, Armidale, NSW, Australia

### Definition and Introduction

Classification proposed by Darwin (1842) recognizes three classes, namely, fringing, barrier, or atoll ignores the multitude and diversity of those continental shelf reefs, which fall between the fringing reefs and the outer barrier reefs near the shelf edge.

Fairbridge (1950, 1967) attempted a genetic classification of these shelf reefs, which would normally fall within the barrier reef type of Darwin (Hopley, 1982).

Maxwell (1968) attempted to elaborate further on the Fairbridge classification scheme, and both believed that they could observe gradational patterns “that lend support to the view that they represent various stages in reef development” (Maxwell, 1968). As Hopley (1982) points out, the classifications were “based on organic and sedimentary growth in response to prevailing wind and wave

conditions during a single period of relatively stable eustatic sea level,” and the reefs had developed exclusively during the Holocene. There was appreciation of the subsequently recognized importance of substrate control of the shape of underlying older reef morphology including antecedent platform shape (Hoffmeister and Ladd, 1944) or karst (Purdy, 1974).

Maxwell (1968, p. 101, Figure 65) recognized the following shelf reef types:

Circular – elliptical shape, radial growth  
 Platform  
 Elongate platform  
 Lagoonal platform  
 Elongate shape  
 Wall  
 Cusplate  
 Prong  
 Composite apron  
 Open ring  
 Open mesh  
 Closed ring  
 Closed mesh  
 Resorbed shape  
 Resorbed

In addition, Maxwell (1968) recognized the high reef of the inner shelf which elsewhere is thought of as being an island namely a “low wooded island.”

The classification scheme envisaged that reefs develop downwind detrital wedges of sediment when in plan resemble horns, which on larger reefs will coalesce to enclose lagoons, and which over time will become infilled with reef sediment to produce platform reefs. Eustatic sea-level variations play little or no part in the morphological variations. Maxwell (1968, p. 100, Figure 64) inferred that the ultimate fate of the reef was “resorption” or chemical dissolution and erosion or reef decay.

### Summary

A considerable amount of research on reef morphology and reef substrates was undertaken in the early 1970s (Flood, 1977; Flood and Orme, 1977), and today it is accepted that the Maxwell (1968) classification is not an evolutionary scheme of morphological development. A more realistic classification of the shelf reef has been presented by Hopley (1982, p. 253, Figure 9.2).

It is now realized that the resorbed shape of Maxwell is indeed the initial stage of Holocene reef growth situated on a pre-Holocene reefal platform where coral colonization during the Holocene sea-level rise has not formed a complete perimeter barrier to the action of waves and that some of the isolated coral growth has occurred on pinnacles of karst towers on the underlying preexisting Pleistocene reef.

An additional modification of the coral reef surface on the circular-elliptical shaped reefs is the “low wooded islands” type of morphological modification, which is characterized by the extensive presence of mangroves. This is a very late stage of modification to the reef-top surface,

and it appears to be related to mangrove colonization subsequent to a slight fall in sea level. These “*low wooded islands*” are common on the inner shelf of the northern Great Barrier Reef, on the reefs within Moreton Bay near Brisbane, and throughout the coral reefs of Southeast Asia and in some inner shelf reef of Belize. Hopley (1982, p. 250, Figure 9.1) of Flood and Orme (1977) depicted in a schematic way, the currently perceived morphological evolution of shelf reefs as a function of tectonic, isostatic, Eustatic, and biological growth factors.

## REEF CLASSIFICATION, RESPONSE TO SEA LEVEL RISE

---

Ian G. Macintyre<sup>1</sup>, A. Conrad Neumann<sup>2</sup>

<sup>1</sup>Smithsonian Institution, Washington, WA, USA

<sup>2</sup>University of North Carolina, Chapel Hill, NC, USA

## Definition

This is a classification of coral reefs based on their response to rising sea levels.

## Introduction

Coral reefs can be classified according to their ability to cope with the post-Pleistocene rise in sea level. Their response to rising sea level is governed by many factors: notably, composition of reef-building communities, changes in the rates of sea-level rise, topography of the substrate when reef growth is initiated, and stress from inimical waters in reef lagoons (Neumann and Macintyre, 1985). The response patterns of reefs have been well documented in studies of reef-growth histories in the Atlantic/Caribbean region but apply to other ocean areas as well. These patterns can be described by a simple analogy comparing reefs to a group of joggers in a race against sea level (Neumann and Macintyre, 1985). Those able to keep pace with the rising sea level are “Keep-Up” reefs; those coming up from behind are “Catch-Up” reefs; and those that are unable to keep up and are left behind exhausted are “Give-Up” reefs (Figure 1).

## The classification

**Keep-Up Reefs.** These reefs have maintained their crests in shallow water throughout their history of accumulation. They usually occur near the shore and were formed during the late phase of the post-Pleistocene sea-level transgression, when there was a significant decrease in the rate of sea-level rise. In the western Atlantic, these reefs are dominated by *Acropora palmata*, a species that is able to accumulate fairly rapidly in exposed areas under heavy wave action. One of the best examples of a “Keep-Up” reef is the fringing reef off Galeta Point, Panama (Macintyre and Glynn, 1976).

**Catch-Up Reefs.** This type of reef establishes itself in deeper water and subsequently catches up with the sea surface because the reef facies accumulates faster than the rise in the sea level. In the western Atlantic, such reefs are usually dominated by the branching coral *Acropora cervicornis*, which can flourish in depths up to 15 m. These reef types are subject to damage and transport by storm activity and thus occur mainly in protected settings, such as Alacran reef of Yucatan (Macintyre et al., 1977) and the Belize Barrier Reef lagoon (Macintyre et al., 2000).

**Give-Up Reefs.** These are usually deeper-water reefs whose growth has been interrupted, thus leaving them stranded in water, too deep for reef accumulation to occur. Stress factors are usually responsible for terminating reef growth, particularly turbidity and low temperatures caused by the flooding of platforms leeward of the reefs. Deeper outer-slope reefs were left stranded by rapid sea-level rises associated with “fresh-water pulses” (Fairbanks, 1989). These deep-water relict reefs are well documented on the insular shelves of the eastern Caribbean (Macintyre, 1972).

A similar classification was proposed by Davies and Montaggioni (1985) for Pacific reefs, particularly those from the Great Barrier Reef.

Reef Classification, Response To Sea Level Rise, Figure 1

### Summary

Coral reefs can be classified by their response to the postglacial rise in sea level, which governs the path of their development and composition of present-day surface communities.

### REEF DRILLING

Dennis K. Hubbard  
 Oberlin College, Oberlin, OH, USA

### Synonyms

Boring; Coring; Reef coring

### Definition

Reef drilling is a method that recovers samples from the interior of a reef, typically using a rotary apparatus operated on the sea floor by divers or from a surface vessel.

### Background

Dating to the writings of DaVinci in the fifteenth century and Mojsisovics' description of alpine reefs four centuries later, natural philosophers asked two fundamental questions: (1) how do we explain oceanic deposits found so far above present sea level, and (2) how did organisms that were limited to the upper few hundred meters of the ocean create deposits that are hundreds or even thousands of meters thick? Tectonic uplift provided a widely accepted answer to the first question. In contrast, the role of subsidence in creating thick reef deposits triggered a heated debate among nineteenth and early twentieth century reef scientists such as Darwin (1842), Geike (1883),

Guppy (1888), Murray (1889), Agassiz, (1902), Gardiner (1904), Daly (1915), and Davis (1923). The main obstacle for Darwin's subsidence theory was the fact that any evidence logically existed beneath the sea and could not be directly observed. The deductive methods championed by Lyell (1830) were not yet accepted by either the body of strict empiricists (e.g., Alexander Agassiz) or those still seeking explanations in one or more "great floods" (e.g., Alexander's father, Louis). The answers were to remain in the submerged strata and beyond the limits of direct observation for a century after Darwin's first suggestion of subsidence as the dominant factor in atoll formation.

While traditional drilling has been in use since at least the nineteenth century, coring to chronicle the interior of modern or Quaternary reefs is relatively new. The Funafuti borings, commissioned by the Royal Society and described in a 1904 issue of *Nature*, were designed more to address Darwin's subsidence hypothesis than to elucidate the relationship between modern reef environments and their ancient counterparts. Half a century later, the shallow-marine carbonates that dominated the upper intervals of the US Geological Survey cores through the Marshall Islands (Ladd and Schlanger, 1960) were simply cataloged as "reefal limestones" and placed in storage once the all-important basalt foundation was encountered, vindicating Darwin's controversial ideas.

So entrenched was the focus on the relative roles of sea-level change (Daly, 1915) versus tectonics (Darwin, 1842) that, as late as 1928, the preeminent geographer William Morris Davis still characterized his chance to observe the surface of the Great Barrier Reef through a viewing box as "an entertaining experience but, as might have been expected, entirely fruitless as far as the origin of the reef is concerned" (described in Hopley, 1982). Two events would change this view forever. The first, the introduction of Emil Gagnan's demand regulator in 1943 (Lawrence, 1997), facilitated direct submarine observations and foreshadowed the rapid rise of marine ecology. The second was the development of a small, submersible reef-drilling system by Ian Macintyre in the 1970s. For the first time, cost-effective and reliable access to the interior of modern reefs was now available.

The early studies of Ian Macintyre, Walter Adey, and Peter Glynn provided important foundations upon which all subsequent Holocene reef studies have built. Since the early descriptions of Holocene reef building in Panama (Macintyre and Glynn, 1976), cores have been recovered from throughout the Caribbean (Adey and Burke, 1976, 1977; Macintyre 1988; Macintyre et al., 1985; Hubbard et al., 1997), Florida (Shinn, 1980; Shinn et al., 1989), French Polynesia (Montaggioni et al., 1997; Cabioch et al., 1999), Hawaii (Grossman and Fletcher, 2004), the western Pacific (Cabioch, 2003), the Great Barrier Reef (Davies et al., 1985; Hopley et al., 2007), the Indian Ocean (Camoin et al., 1997; Montaggioni and Faure, 1997; Braithwaite et al., 2000), and Japan (Yamano et al., 2001), among others.

Early coring studies emphasized the large-scale evolution of facies patterns and reef fabrics that might be integrated into hydrocarbon exploration models. This focus quickly broadened to include the role of ocean processes and changes in sea level in controlling reef development on a millennial scale. More recently, attention has shifted to the dramatic decline in the world's reefs, with fundamental questions being asked about the mechanisms that are responsible and the extent to which anthropogenic factors have been in play. In the words of Wendell Berry, "We cannot know what we are doing until we know what nature would be doing if we were doing nothing" (*Home Economics*). Cores through Holocene reefs provide our only possibility to examine reefs that were identical to those of today, except for a notable lack of human influence. Thus, they provide opportunities to make links with the past, to understand the origins of present-day reefs, and to make projections about how increasing anthropogenic pressures may change reef trajectories in the future.

The following focuses on three topics. First, the drilling method is generally described. The intent is not to provide a "how to" primer, but to describe the methodology in its most basic form. Second, an overview of the ways that reef cores can be used describes the kinds of information that can be derived from them. And finally, potential issues with extrapolating from cores to the larger reef interior are considered. It is important to understand problems that are inherent in this approach. Nevertheless, we need to be mindful that reef cores pretty much represent "the only game in town" when it comes to examining the underpinnings of the present-day coral-reef community or the events that have led up to where we find ourselves today.

Early bore holes along the northern Great Barrier Reef (Richard and Hill, 1942; Maxwell, 1962) provided information on the evolution of that carbonate system. Since then, large shipboard systems have made significant contributions to our understanding of the larger-scale questions that dominated the nineteenth and twentieth centuries. Longer-term platform evolution along the Great Barrier Reef was detailed using deeper cores through the outer Great Barrier Reef (Webster and Davies, 2003; Braithwaite et al., 2004). Cores through the deep reefs off Barbados have provided invaluable information on patterns of sea-level change that extend beyond the histories derived from reefs within the range of normal Self Contained Underwater Breathing Apparatus (SCUBA) diving. This chapter focuses on the more modest systems that have provided so many of us with an opportunity to carefully examine the relationships between reef fabric, oceanographic process, and rising sea level over the past 12,000 years.

### The coring method

While individual drill rigs vary in size, complexity and their ability to penetrate further into the reef, all owe their origins to the prototype developed at the Smithsonian Institution and described in Macintyre (1975). In this first

iteration, hydraulic fluid was delivered to a modified Ackley impact wrench via hydraulic hoses from a pump that was driven by a four-cylinder Triumph gasoline engine. Core was collected in a rotating barrel that was connected to the wrench. A separate pump provided water to the rotating drill bit for cooling and clearing away of debris generated by the drilling process. Over the years, researchers have experimented with different power supplies, larger ones for greater penetration, smaller ones for increased portability, but they all share the basic design of the original Macintyre system.

Core is typically recovered in 1.5-m (5-ft) sections, the most common length for commercially available core barrels (Figure 1a). Larger-diameter, single-walled barrels have been used to recover short reef cores or to sample individual coral heads. However, most reef-coring systems use a 10–15 cm (diameter), double-walled barrel in which an inner cylinder is isolated from its outer counterpart by a swivel that allows the core to slip into the stationary inner tube while the outer barrel and drill bit rotate to auger into the reef (Figure 2).

In earlier systems, smaller-diameter extension rods were added to the top of the core barrel after each recovery. In this method, the complete length of drill string had to be removed, section by section, each time a core was recovered. More recently, “wire-line” systems have been developed that allow remote recovery of the inner core barrel without removing the drill string. In these systems, the extension rods are of the same diameter as the core barrel. The uppermost section of drill pipe is

separated from the drill motor using pipe wrenches (Figure 1b), and a “messenger” is lowered through the interior of the drill string to lock onto and pull up the inner core barrel.

The advantage of this approach is threefold. First, it greatly reduces the time and effort required to recover the core. Second, because the extension rods stay in place throughout coring, they prevent contamination by material falling from the walls of the hole during core recovery. Finally, because the extension rods are of the same diameter as the outer core barrel, this eliminates the potential for cave-in to jam the core barrel at the point where the drill string changes size.

Once the core is recovered, each piece is numbered from top to bottom and marked to indicate its original orientation. Loose rubble is placed in bags that are likewise numbered in sequence. Notes describing changes in drilling difficulty throughout the core interval are used to create a log in which samples are placed into the best possible vertical context (Figure 3). Coral types are added, based on either field or laboratory determinations, and are ideally identified to species. To the extent possible, intervals of sediment, rubble, and open voids are placed on the log using the notes taken by the operators while drilling.

The earliest drilling systems were used primarily in shallow water and were suspended from a tripod (Figure 4), a configuration still used by many researchers. The drill and the core barrel are suspended on a wire, and a small hand winch is used to raise the drill after a core is

**Reef Drilling, Figure 1** (a) Typical core barrel for drilling. The bit in the foreground drills a hole in the reef. A sleeve inside the barrel is suspended on a swiveling mechanism that allows the core to slide into the stationary inner barrel (Fig. 2). (b) Divers breaking the joint between the core barrel and the first section of extension rod. This provides access to the inner core barrel using a “messenger” that is lowered into the hole (Photos by permission of the author).

**Reef Drilling, Figure 2** Diagram illustrating a double-walled core barrel drilling into the reef (stippled pattern). The outer assembly consists of a core barrel (1) and either a diamond or carbide drill bit (2). An inner barrel (3) is suspended on a swivel mechanism (4) that allows the inner sleeve to remain stationary while the outer cylinder rotates. As the bit grinds into the reef, samples (5) slide into the stationary inner barrel. A water swivel (6), attached to the top of the core barrel or the uppermost section of extension pipe allows water to enter from a stationary hose (7) while the inner mechanism maintains a connection between the drill string and the drill motor (not shown, but attached to the top of the water swivel). Water flow passes through channels in the swivel mechanism, moves down along the annulus between the inner and outer core barrels (8) and out along the edge of the drill bit. Small bits of debris generated by drilling plus any sediment are flushed out of the hole (9).

completed. The wire is usually left slack during drilling, and weight is added (often in the form of graduate students standing atop the drill motor: [Figure 4a](#)) to speed penetration. On exposed reef flats, unmodified commercial core rigs can be used ([Figure 5a](#)). In some cases, small platforms that can be raised on legs have been used to provide a dry environment for coring operations along the reef crest ([Figure 5c](#)). This requires additional logistical support and can be used only where water depth over the reef crest allows the platform to be floated into place. In deeper water, the simpler tripod can still be used or can be

replaced by an air bag that provides buoyancy to raise the drill string and move equipment on the bottom ([Figure 5b](#)). The lift bag can be combined with a block-and-tackle system that is attached to the substrate to apply constant pressure to the bit, a particularly difficult venture when coring horizontally as in [Figure 5d](#).

## What we have learned from reef cores

### Paleoenvironment

Coring is the primary method for directly sampling the interior of a modern reef. At the most basic level, a core tells a story of reef development at a single point. By taking multiple cores, the investigator can start to assemble a three-dimensional story. The present-day distribution of coral species (or morphologies) can be used to interpret which areas on a modern reef surface are represented by the corals recovered from its interior. Variations in coral type within a core may reflect changing water depth, shifts in wave energy or gradients in other physical- and chemical-oceanographic factors. Radiometric dating of individual coral samples provides a temporal context within which these changes likely occurred. Ideally, cores are taken along transects ([Figure 6](#)) to provide important information about spatial variability within the reef, as well as changes in reef morphology and community structure over time. Interpretations from a single core can provide an incomplete picture that is at odds with the larger fabric of the entire reef.

In the example provided in [Figure 6](#), from southwestern Puerto Rico, coral type is represented by open symbols (branching corals) and black semicircles (massive species). The dashed timelines, based on calibrated radiocarbon dates, represent the reef surface at 1,000-year intervals. At this site, the early reefs occurred close to the shelf edge and atop a shallower and broader platform some 30 m landward. They were populated by branching *Acropora palmata*, the dominant Caribbean reef crest species for the past million years. The lowest section of the reef is made up of debris derived from bioerosion of unpreserved corals that likely grew along the antecedent Pleistocene margin (the “brick” pattern). Based on available sea-level curves, the area had flooded by 12,000 years ago but, while corals were undoubtedly present, conditions after shelf flooding prevented reef accretion until sometime around 10,000 years ago. As the outer reef continued to build, massive corals formed in what was probably a protected backreef area behind the outermost ridge. *A. palmata* was the primary framebuilder at that time and remained so until circa 6,500 years ago, when reef accretion stopped along this and many other Caribbean shelf margins. The dominance of branching corals throughout the history of this reef is in marked contrast to the present-day reef community of mostly massive scleractineans and soft corals. More detailed information on the evolution of specific reefs and the paleoclimate associated with their development is provided elsewhere in this volume.

**Reef Drilling, Figure 3** Core logs from three different studies used to characterize the nature of the reef interior. (a) Generalized log showing the core intervals (horizontal ticks) and the dominant constituents found in each section of the core. Individual samples are not indicated. (b) Summary log delineating the interpreted facies (in this case, branching, massive, and encrusted corals). (c) Detailed log showing the specific locations and extent of each recovered sample (*left*), plus an interpretation of the cored section (*right*) based on recovered samples and detailed drilling notes.

**Reef Drilling, Figure 4** Typical deployments of tripod-based drills on the reef crest (*left* – St. Croix, US Virgin Islands; *right* – Antigua). A hand-winch system is used to raise the drill string. The lifting wire is generally left slack and weight is added to facilitate drilling. Note the hoses that deliver water and hydraulic power from a system on a small vessel located nearby. This system has been operated from a 15-ft Boston Whaler at low cost and with minimal logistical support (Photos by permission of the author).

### Modern reef environments and fossil reef facies

When trying to understand a fossil reef, whether in outcrop or a series of cores, geologists think in terms of reef *facies* – visually distinct assemblages of preserved corals and sediment that can be related to the zonation patterns biologists see on the surface of the reef today. A reef facies is the rock equivalent of the environment of deposition in

which the preserved organisms originally lived and died. As will be discussed below, a number of factors conspire to make the end product in the geologic record an imperfect representation of what actually lived in and on the reef in the past. Nevertheless, if we confine ourselves to the primary constituents and keep some of these pitfalls in mind, we can make realistic inferences within an

**Reef Drilling, Figure 5** Different coring systems in use today. (a) Land-based system used by French researchers to drill through Pacific and Indian Ocean atolls (Photo courtesy of Guy Cabioch). (b) In deeper water, the tripod can be replaced by an air bag that provides buoyancy to move equipment and lift the drill after coring is completed. (c) Along submerged reef crests, a small jack-up platform allows dry operation (Photos B and C courtesy of Charles Fletcher). (d) Drilling on the vertical wall of a submarine canyon required a lift bag and a block-and-tackle system. Cables run from the drill motor, through pulleys attached to the reef, back to a pulley on the drill motor, and then up to an inflated air bag. This action converts lift provided by the air bag into the inward force required to drill. This method has also been used in vertical deployments where simply adding weight to the drill is inconvenient (Photo by permission of the author).

**Reef Drilling, Figure 6** Cross section through a shelf-edge reef off the southwestern corner of Puerto Rico. The distribution of branching (white symbols) and massive corals (black hemispheres) reflects conditions that are favorable to each (e.g., distance from the reef front and paleo-water depth). Time lines (*dashed*) are based on corrected radiocarbon dates, and provide important information on surface morphology through time (From Hubbard (2008), with permission by Springer).

individual fossil reef or between reefs in different settings. For example, a preponderance of branching acroporids in a Quaternary Caribbean reef likely reflects moderate to high wave energy and low sedimentation in shallow water where light is abundant (Figure 7). Moving down the reef

front, a progressive shift toward species and morphologies that are better adapted to declining light, reduced wave action, and perhaps greater sedimentation creates a predictable pattern that can be used to relate facies within a fossil reef to environmental zones on the surface of the

**Reef Drilling, Figure 7** (a) Underwater photograph of a modern Caribbean reef crest in the US Virgin Islands. The branching coral is *A. palmata*, which dominated Caribbean reef crests until near extirpation by disease in the 1980s. (b) Photograph of in-place, Pleistocene *A. palmata* on the south coast of Curacao, reflecting a similar environment. The live community in (a) sits within the “Branching-Coral Zone” on the modern reef crest; the fossil community in (b) is part of the “reef crest facies” or the “branching-coral facies,” suggesting a similar place on the reef 125,000 years ago (Photos by permission of the author).

same reef today. Because of the greater diversity in Pacific reefs, this comparison is less straightforward, but the same factors still control reef zonation. Most of the important modern coral species have been in existence since at least the early Quaternary, making these sorts of comparisons easier than is the case when dealing with older deposits. However, we can probably still be relatively confident in our comparisons as far back as the Triassic, when scleractinians corals developed their relationship with photosynthesizing zooxanthellae.

### Sea level versus reef accretion

As sea level rises, predictable shifts in community structure will occur, depending on the ability of reef building to keep pace (Neumann and Macintyre, 1985; Davies et al., 1985). When sea level is rising faster than the reef can aggrade, the reef will lag behind. This condition results in a gradual change toward species adapted to deeper water (primarily massive, fine-branching, and platy corals). If this pattern persists long enough, the reef will be abandoned once light levels become too low to support photosynthesis (i.e., a “give-up reef” of Neumann and Macintyre, 1985). This will also be reflected at a larger scale in (a) upslope retreat of the main reef facies, (b) backstepping (i.e., a landward shift in the locus of reef accretion) or (c) reef drowning (Figure 8).

Conversely, if sea level slows, as it has done for the past 6,000–7,000 years, some reefs that were being left behind will begin to “catch up” once the rate of sea-level rise slows to less than the reefs’ ability to build vertically. The sequence of corals will reflect progressively shallower water. If reef accretion and sea-level rise are roughly equal, water depth over the reef will remain constant. In this scenario, the “keep-up” reef will generally remain close to sea level and shallow-water species will dominate throughout the core (e.g., rapidly growing *Acropora palmata* in the Caribbean). In either case, facies geometry is usually dominated by vertical accretion (Figure 8). However, once sea level slows to the point that accommodation space is

**Reef Drilling, Figure 8** Reef-accretion patterns versus sea-level rise. When sea level is rising more slowly (i.e., near high- and low-stands: indicated by “+”), reefs will either build vertically when accretion and accommodation space are created nearly equally (catch-up or keep-up reefs of Neumann and Macintyre, 1985) or will prograde if reef building is the dominant factor in the equation (keep-up reefs). During intervals of rapid sea-level rise (“–”), reefs will “give up” by retreating upslope, backstepping (i.e., a new reef will form at a shallower and more landward site where conditions are appropriate for reef initiation), or simply being abandoned in place, depending on the rate of sea-level rise and the character of the underlying bathymetry. Thus, the facies geometry becomes a useful tool for understanding past patterns of sea-level change Hubbard (1997).

created more slowly than carbonate is produced to fill it, progradation will join upward aggradation and the reef crest will build “up-and-out.”

While simple models based on a vertical sequence of corals can provide a good conceptual framework for tying shifts in community structure to sea-level rise, these relationships can be complicated by changing oceanographic conditions. For example, a shift to a more vigorous wave climate can favor shallower-water species without

changing depth (Adey and Burke, 1977). Conversely, increased sedimentation or nutrient input can shift environmental boundaries upward (Acevedo et al., 1989).

On a larger scale, the patterns summarized in Figure 8 provide a generalized picture of changing facies geometry as rising sea level creates accommodations space and vertically accreting reefs try to fill it. However, a net landward shift of the reef crest over time does not preclude the downslope movement of detritus. Conversely, when the reef crest builds seaward as it tracks rising sea level, reef-derived materials can still move landward either within or between facies. In particular, as the reef builds close to sea level, small-scale transport patterns can vary markedly depending on reef geomorphology. After Hurricane Hugo, detrital transport was almost exclusively downslope and seaward where the Buck Island forereef sloped more steeply. However, where the forereef was gentler, material stripped from the face of the reef moved up and over the crest, resulting in 10 m of landward progradation of the reef flat in less than 24 h (Hubbard et al., 1991; Hubbard, 1992).

Thus, small-scale variations can exist within any larger-scale pattern. Nevertheless, the general picture provided by either changing corals or facies geometry revealed by cores still provides a reliable sense of the interaction of the larger reef system, the smaller-scale coral community, and rising (or falling) sea level.

### Environmental proxies
